## Executive Summary

This study was conducted between July 2008 and May 2009 in an effort to understand the effect of wastewater effluent discharge from the Sacramento Regional Wastewater Treatment Plant (SRWTP) on nutrient concentration and phytoplankton abundance and productivity within the Sacramento River between the City of Sacramento and Rio Vista, CA. Five different experimental approaches were used during the study: (1) River characterization of inorganic nutrients and phytoplankton (2) Experimental grow-outs to investigate the time course of potential phytoplankton bloom development in the Sacramento River (3) Sacramento River water aging experiments to investigate the potential for bacterially mediated nitrification (i.e. ammonium ( $\text{NH}_4$ ) conversion to nitrite ( $\text{NO}_2$ ) and nitrate ( $\text{NO}_3$ ) (4)  $\text{NH}_4\text{Cl}$  addition experiments to evaluate the hypothesis that  $\text{NH}_4$  inhibits phytoplankton  $\text{NO}_3$  uptake and decreases phytoplankton growth rates (5) Wastewater effluent addition experiments to evaluate whether wastewater discharge alters primary production and phytoplankton nitrogen uptake.

River characterizations shows that SRWTP discharge has a profound effect on river nutrient concentrations with an increased concentration of  $\text{NH}_4$  and phosphate ( $\text{PO}_4$ ) downstream of the outfall; the peak in  $\text{NH}_4$  concentration does not always occur at the outfall location but further downstream. Nutrient concentrations varied substantially on a seasonal basis. The spatial distribution of  $\text{NH}_4$ ,  $\text{NO}_2$ , and  $\text{NO}_3$  suggest nitrification is occurring downstream of the SRWTP. We observed a consistent north to south gradient of declining chlorophyll-a concentrations and fluorescent particle abundance (indicative of phytoplankton). Primary production sometimes declined from north to south consistent with the trends in chlorophyll-a. Phytoplankton  $\text{NH}_4$  uptake increased just downstream of the wastewater discharge, presumably in response to higher  $\text{NH}_4$  concentration supplied via SRWTP and then declined downstream. Phytoplankton  $\text{NO}_3$  uptake was high at stations upstream of the SRWTP discharge, consistent with relatively high primary production found at the upstream stations.  $\text{NO}_3$  uptake decreased to near detection limits ( $0.02 \mu\text{mol L}^{-1} \text{d}^{-1}$ ) at stations downstream of the SRWTP. The shut down of phytoplankton  $\text{NO}_3$  uptake is the result of the well described phenomenon of  $\text{NH}_4$  inhibition of phytoplankton  $\text{NO}_3$  uptake. The sum of phytoplankton  $\text{NO}_3$  and  $\text{NH}_4$  uptake declined in the downstream direction.

Results from experimental grow-outs suggest that after removing light limitation phytoplankton bloom magnitude in the Sacramento River at RM-44 (downstream of SRWTP discharge) and GRC (upstream of SRWTP discharge) is likely determined by dissolved inorganic nitrogen (DIN) availability. Grow-out experiments conducted at RM-44 produced more chlorophyll-a than experimental grow-outs conducted at GRC. Phytoplankton appeared to take advantage of additional DIN, whether supplied as  $\text{NO}_3$  or  $\text{NH}_4$  in experiments conducted with water from GRC, or in the form of  $\text{NH}_4$  supplied in the wastewater effluent (at RM-44) to produce greater biomass.

Sacramento River water aging experiments from RM-44 and GRC suggested that nitrification (microbially mediated stepwise conversion of  $\text{NH}_4$  to  $\text{NO}_2$  and  $\text{NO}_3$ ) may occur in the river but only on time scales of 7 to 14 days. The addition of  $\text{NH}_4$  via SRWTP discharge likely increases rates of this process relative to locations upstream of SRWTP (GRC) where  $\text{NH}_4$  concentrations were lower. There was little evidence of nitrification occurring in aged river

water on time scales of 7 days or less, even in an experiment in water with elevated  $\text{NH}_4$  (RM-44).

During April 2009, experimental additions of  $\text{NH}_4\text{Cl}$  up to  $+50 \mu\text{mol L}^{-1}$  resulted in a significant reduction in primary production (by ca. 8%). In contrast, supplements of  $\text{NH}_4\text{Cl}$  to water collected at GRC with additions of  $0.25 \mu\text{mol L}^{-1}$  to  $100 \mu\text{mol L}^{-1}$  showed no effect on primary production during short-term (4-hr) experiments during May 2009. Also during May 2009, additions of  $\text{NH}_4\text{Cl}$  enhanced phytoplankton  $\text{NH}_4$  uptake up to  $\text{NH}_4$  concentrations of ca.  $4 \mu\text{mol N L}^{-1}$  (i.e. half-saturation constant,  $K_m$ , for  $\text{NH}_4$  in the Sacramento River). In contrast, additions of  $\text{NH}_4\text{Cl}$  reduced phytoplankton  $\text{NH}_4$  uptake during the experiment conducted in April 2009. This suggests that  $\text{NH}_4$  concentrations greater than  $4 \mu\text{mol N L}^{-1}$  will not further enhance phytoplankton  $\text{NH}_4$  uptake but may at times reduce  $\text{NH}_4$  uptake. Phytoplankton  $\text{NO}_3$  uptake was reduced to near detection limits with small experimental additions of  $\text{NH}_4\text{Cl}$  ( $\ll 1 \mu\text{mol L}^{-1}$ ) during both April and May 2009 experiments.

Experimental additions of SRWTP effluent (containing  $\text{NH}_4$ ), from  $0.25 \mu\text{mol NH}_4 \text{L}^{-1}$  to  $100 \mu\text{mol NH}_4 \text{L}^{-1}$  resulted in decreased primary production rates (up to ca. 36% of controls); the decline in primary production became evident at effluent- $\text{NH}_4$  concentrations greater than  $8 \mu\text{mol N L}^{-1}$ . Similarly,  $\text{NH}_4$  supplied by SRWTP effluent decreased phytoplankton  $\text{NH}_4$  uptake at concentrations greater than  $4 \mu\text{mol N L}^{-1}$  by as much as 29%. Consistent with results for  $\text{NH}_4\text{Cl}$  addition experiments, phytoplankton  $\text{NO}_3$  uptake was also reduced to near detection limits with effluent- $\text{NH}_4$  additions less than  $1 \mu\text{mol NH}_4 \text{L}^{-1}$ . The concentration threshold of  $8 \mu\text{mol N L}^{-1}$  represents a wastewater effluent dilution of greater than 200:1 (based on an undiluted effluent  $\text{NH}_4$  concentration of  $1933 \mu\text{mol N L}^{-1}$ ), significantly higher dilution than required under the current SRWTP permitting 14:1 (C. Foe, pers comm.);  $\text{NH}_4$  concentrations  $>8 \mu\text{mol L}^{-1}$  were consistently observed at stations downstream of the SRWTP during river characterizations and were attributed to the SRWTP discharge.

These results indicate that SRWTP discharge has an effect on inorganic nutrient concentrations and may have an effect on phytoplankton processes in the Sacramento River downstream of Garcia Bend. Experimental grow-outs reveal that populations at upstream locations (GRC and RM-44) are in a physiologically unimpaired condition. This is in stark contrast with results obtained previously with grow-outs conducted over 5 to 7 days at Rio Vista (Wilkerson,  $\text{NH}_4$  Summit). The two experimentally determined effects of effluent additions are: (1) the direct shut down of phytoplankton  $\text{NO}_3$  uptake by the  $\text{NH}_4$  supplied with SRWTP effluent and (2) the negative effect of sewage effluent on primary productivity and phytoplankton  $\text{NH}_4$  uptake. The decline in primary production observed *in situ* downstream of the SRWTP is consistent with the results using experimental additions of SRWTP effluent and  $\text{NH}_4\text{Cl}$  which demonstrate an impact to phytoplankton processes in an experimental setting and provide evidence of a potential negative impact to phytoplankton as a result of SRWTP effluent  $\text{NH}_4$  discharge in the Sacramento River.

## 1.0 Study Background

Compared to most temperate estuarine systems, primary production and rates of phytoplankton nitrogen uptake are low in Suisun Bay and in the Sacramento River as far upstream as Rio Vista. This has also been documented as a long-term decline in phytoplankton abundance in the San Francisco Bay Estuary (SFE) (Jassby 2008). Jassby et al. (2002) estimated that annual primary productivity in the Delta decreased by 43% between 1975 and 1995 and showed that phytoplankton biomass trends were neutral in Suisun Bay and positive in the Delta between 1996-2005 (Jassby, 2008).

Several physical and biological factors are known to influence phytoplankton biomass and productivity in this system. The SFE is not a low nutrient system; light (controlled by turbidity and seasonal irradiance) and freshwater flow are considered key factors controlling primary production. Filtration or grazing by the invasive clam (*Corbula amurensis*) is considered a major contributor to the decrease in phytoplankton abundance that occurred in Suisun Bay and the western Delta after its arrival in 1986 (Alpine & Cloern, 1992; Jassby et al. 2002). *Corbula* is not present in the freshwater reaches of the San Francisco Estuary Delta (the focus of the present study). However, another bivalve, *Corbicula sp.* is present in the freshwater region of the Delta.

Wilkerson et al. (2006) showed that spring blooms of phytoplankton in the northern SFE occurred when at least two conditions were satisfied: (1) vertical stratification driven by salinity that improved light conditions, and (2) ambient concentrations of  $\text{NH}_4$  below a threshold of ca.  $4 \mu\text{mol L}^{-1}$  ( $1 \mu\text{mol N L}^{-1} = 0.014 \text{ mg N L}^{-1}$ ; i.e.  $4 \mu\text{mol L}^{-1} = 0.056 \text{ mg N L}^{-1}$ ). Tracer experiments using water from the northern SFE indicated that above this  $\text{NH}_4$  threshold, phytoplankton almost exclusively took up  $\text{NH}_4$  (leaving the  $\text{NO}_3$  pool little changed), but the

NH<sub>4</sub> uptake was not accompanied by significant increases in algal biomass (Dugdale et al. 2007). When NH<sub>4</sub> levels dropped below this threshold (~4 μmol L<sup>-1</sup>), chlorophyll-a increases were observed. It was not until NH<sub>4</sub> dropped below about 1 μmol L<sup>-1</sup> that rapid NO<sub>3</sub> uptake commenced and rapid growth of phytoplankton took place. As a consequence of these studies in the SFE, ambient NH<sub>4</sub> levels, and hypothesized suppression of phytoplankton blooms by NH<sub>4</sub>, have been added to the list of factors that may be affecting the base of the pelagic food web in the SFE. Preliminary results from ongoing CALFED research suggest that NH<sub>4</sub> inhibition of NO<sub>3</sub> uptake may occur in the freshwater reaches of the estuary (Sacramento River at Rio Vista).

The studies described above suggest that ambient NH<sub>4</sub> levels above ~4 μmol L<sup>-1</sup> may prevent bloom forming phytoplankton taxa (especially diatoms) from accessing the larger NO<sub>3</sub> pool in the northern estuary. The study described herein is an initial investigation into whether the NH<sub>4</sub> and NO<sub>3</sub> uptake interactions observed in experiments using water from the northern estuary will occur in fresh water from the Sacramento River, where the Sacramento Regional Wastewater Treatment Plant (SRWTP) effluent supplies NH<sub>4</sub>. Several terms are used to describe interactions between NH<sub>4</sub> and NO<sub>3</sub> use by phytoplankton, such as “inhibition”, “suppression”, and “preferential uptake”. Generally, an indirect interaction between NH<sub>4</sub> and NO<sub>3</sub> is termed preference, and a direct interaction between NH<sub>4</sub> and NO<sub>3</sub> uptake is termed inhibition. NH<sub>4</sub> preference means that NH<sub>4</sub> is more readily utilized than NO<sub>3</sub> although this may not result in more rapid growth than on NO<sub>3</sub>. Inhibition results when the presence of one nitrogen source prevents or reduces the uptake of the other. Enzymatic disruption of NO<sub>3</sub> reductase during NH<sub>4</sub> assimilation is one of the proposed mechanisms for true inhibition (Dortch 1990).

The SRWTP discharges an average of 141 million gallons per day (mgd) (representing nearly 60% of all wastewater discharges in the SFE Delta) of secondarily treated municipal wastewater effluent to the Sacramento River immediately downstream of the Freeport Bridge (NPDES, 2009). The SRWTP serves 1.3 million people in the City of Sacramento and surrounding communities and is currently requesting an increase in permitted average dry weather discharge from 181 mgd to 218 mgd (NPDES, 2009).

MacIsaac et al. (1979) performed experiments to observe the effects of treated wastewater on phytoplankton populations in Southern California. Serial enrichments of seawater with treated wastewater or a sterile NH<sub>4</sub>Cl solution (of similar NH<sub>4</sub> concentration to the treated wastewater) as a control were made and uptake of <sup>15</sup>N and <sup>14</sup>C measured. The authors described suppression of NO<sub>3</sub> uptake and NH<sub>4</sub> uptake. Suppression of carbon uptake (primary productivity) also occurred, but at higher concentrations of NH<sub>4</sub> (both alone and in treated wastewater) than for NO<sub>3</sub> and NH<sub>4</sub> uptake suppression. In the Sacramento River, SRWTP treats mainly residential wastewater with a high-purity oxygen activated sludge secondary treatment and chlorination / dechlorination disinfection before discharging a highly diluted final effluent (2% of river flows) into a freshwater receiving environment.

The study described here was conceived to investigate whether the NH<sub>4</sub> effects on primary production that have been observed in the northern SFE also occur in the Sacramento River as a result of wastewater effluent discharge by SRWTP, a secondary level (i.e. discharges primarily NH<sub>4</sub>) discharger. Specifically, the study was designed to answer the following research questions:

1. Is the SRWTP a source of  $\text{NH}_4$  to the Sacramento River?
2. Does elevated  $\text{NH}_4$  concentrations in the Sacramento River inhibit phytoplankton N uptake *in situ*? Does SRWTP effluent inhibit phytoplankton N uptake in an experimental setting?
3. Do elevated  $\text{NH}_4$  concentrations reduce primary production or the potential for phytoplankton blooms *in situ* in the Sacramento River? Does SRWTP effluent inhibit primary production in an experimental setting?
4. Is there any indication that phytoplankton species composition changes occur *in situ* as a result of SRWTP effluent (including  $\text{NH}_4$ ) discharge?

## 2.0 Study Components / Experimental Design

The scope of work for this research project was developed under agreement 06-447-300-0 between the California State Water Quality Control Board and the Romberg Tiburon Center – San Francisco State University (RTC-SFSU); this agreement contained eight TASKS that were developed out of convenience for funding rather than as the experiments were conceived or conducted (referred to here under Section 2, Experimental Design). The results presented in this document (in Section 3, Results) reflect how the experiments were conducted rather than how they were organized by TASKS. Table 1 is provided to aid the reader in determining how each of the sections described below (Section 4: Results) reflects each TASK as outlined in the agreement.

### 2.1 River Characterization

This study required characterization of nutrients and phytoplankton in the Sacramento River near the Sacramento Regional Wastewater Treatment Plant (SRWTP). This was accomplished twice during 2008 (21 July and 12 November) and three times (9 March, 6 April, 8 May) in 2009 (Table 2) by sampling an eight (8) station transect (Table 3) with three stations upstream of the SRWTP discharge near station RM-44 and five stations downstream of the SRWTP. Surface water samples were collected at each station along with additional vertical profiles of *in vivo* chlorophyll-a using a Wetlabs fluorometer and photosynthetically active radiation (PAR) using a LiCor submersible PAR sensor.

Detailed explanations of nutrient and phytoplankton sample collection, handling and analysis are provided below (Section 3). Briefly, at each station Niskin bottle water samples were collected for nutrients and placed on ice and returned to the lab to determine  $\text{NO}_3$ ,  $\text{NO}_2$ , silicate ( $\text{Si}(\text{OH})_4$ ),  $\text{PO}_4$ ,  $\text{NH}_4$ , and urea. Separate samples were collected for determination of dissolved inorganic carbon (DIC) concentrations and to estimate number of fluorescing particles, *in vitro* chlorophyll-a concentration in all phytoplankton cells (using GF/F filters with nominal pore size of 0.7  $\mu\text{m}$ ) and in larger phytoplankton cells using Nucleopore filters with pore size of 5  $\mu\text{m}$ . In addition, during November 2008 and all of 2009 primary production and phytoplankton nitrogen uptake were assessed using  $^{13}\text{C}$  and  $^{15}\text{N}$  ( $\text{NH}_4$  and  $\text{NO}_3$ ) tracer techniques in 24-hr incubations. These transects were designed to understand the potential role that the SRWTP effluent discharge had on Sacramento River nutrients, turbidity and phytoplankton biomass.

## ***2.2 Aging Experiments***

On 21 July 2008, 20-L (LDPE cubitainers) water samples from two locations in the Sacramento River, upstream of SRWTP at Garcia Bend (GRC) and just downstream of the SRWTP (at RM-44), were collected during the River Characterization (Section 3). These samples were returned to RTC, held in the dark at ambient temperature (21°C) and “aged” for eight weeks. Each of the carboys was sampled weekly for the eight week period for analysis of  $\text{NO}_3$  and  $\text{NH}_4$  concentrations as well as  $\text{PO}_4$  and  $\text{Si}(\text{OH})_4$ . The objective of this experiment was to determine whether nitrification (i.e. sequential oxidation of  $\text{NH}_4$  to  $\text{NO}_2$  and  $\text{NO}_3$ ) was likely to occur in the Sacramento River.

## ***2.3 River Sample Grow-out Experiments (“Grow-Outs”)***

Twice during 2008 (21 July and 12 November) and twice during 2009 (9 March and 8 May) water was collected from two locations in the Sacramento River - upstream of SRWTP (GRC) and just downstream of the SRWTP (RM-44) and used to fill triplicate 20-L LDPE cubitainers. These were the same upstream reference and downstream stations that were used for aging experiments (Section 2.2). The cubitainers were transported back to RTC in coolers and incubated in bay water-cooled tubs under natural ambient solar irradiance. Due to the natural suspended sediments in the bay, light was attenuated to ca. ~40% of surface irradiance within the incubation tubs. Grow-outs were sampled daily for the first 96-hr and then after 144-hr and 216-hr for nutrients ( $\text{NO}_3 + \text{NO}_2$ ,  $\text{NH}_4$ ,  $\text{PO}_4$ ,  $\text{Si}(\text{OH})_4$ ), DIC, chlorophyll-a, fluorescent particles and temperature. After 96-hr, nutrient limitation was observed in grow-out experiments and so analysis of results was limited to the first 96-hr. During 2009 additional 20-L cubitainers were collected at GRC and amended with  $\text{NO}_3$  and  $\text{NH}_4$  to concentrations comparable to the dissolved inorganic nitrogen concentrations found at RM-44. In addition, during 2009, primary production and phytoplankton nitrogen uptake were assessed daily in the grow-outs using  $^{13}\text{C}$  and  $^{15}\text{N}$  ( $\text{NH}_4$  and  $\text{NO}_3$ ) tracer techniques. The goal of these experiments was to determine the potential for phytoplankton biomass accumulation at stations upstream (GRC) and downstream (RM-44) of the SRWTP under non-light limited conditions simulating a phytoplankton bloom.

## ***2.4 Clean $\text{NH}_4\text{Cl}$ Addition Experiments***

On 6 April 2009 water was collected at GRC for short term (4-hr) primary productivity experiments with 3 experimental additions of  $\text{NH}_4$  (added as  $\text{NH}_4\text{Cl}$ ).  $\text{NH}_4$  was added at concentrations of  $+1 \mu\text{mol L}^{-1}$ ,  $+4 \mu\text{mol L}^{-1}$ , and  $+50 \mu\text{mol L}^{-1}$   $\text{NH}_4$ . Incubations were performed in triplicate 160-ml incubation bottles using  $^{14}\text{C}\text{-NaHCO}_3$  under natural light that had been attenuated to 50% of surface PAR using window screening. The goal of this experiment was to evaluate the potential for acute  $\text{NH}_4$  inhibition of primary production in the Sacramento River as had been previously shown for other regions of the northern San Francisco Estuary (see study background).

## ***2.5 Diluted Effluent Experiments***

This experimental protocol follows closely that used in experiments on Los Angeles effluents (MacIsaac et al. 1979). A flow-weighted 24 hour composite of dechlorinated final effluent from SRWTP was provided by C. Foe on 28 April 2009 and transported to the Romberg

Tiburon Center by the Central Valley Regional Water Quality Control Board (CVRWQB). Nutrient concentrations ( $\text{NH}_4$ ,  $\text{NO}_3$ , and  $\text{PO}_4$ ) in the effluent were analyzed so that nutrient additions based upon the effluent concentrations of  $\text{NH}_4$  and  $\text{NO}_3$  could be made.

The following day, four sets of 20 280-ml incubation bottles were filled with water collected at GRC on 28 April 2009 by C. Foe. To one set of incubation bottles serial additions of SRWTP effluent were added to make an addition series of 10 concentrations of  $\text{NH}_4$  from 0 to  $100 \mu\text{mol N L}^{-1}$ . To the second set of incubation bottles serial additions of  $\text{NH}_4\text{Cl}$  were added to make a parallel set of additions from 0 to  $100 \mu\text{mol N L}^{-1}$ . Once the additions were made, isotopic tracers,  $^{15}\text{NO}_3$ ,  $^{15}\text{NH}_4$  and  $^{13}\text{C}$  were added at approximately 10% of ambient  $\text{NO}_3$ ,  $\text{NH}_4$ , and DIC concentrations. The third and fourth sets of bottles were used for  $^{14}\text{C}$ -based primary production estimates. Samples were then incubated for 6-hr in flowing bay-water tables under natural light attenuated to 50% of surface irradiance using window screening. The goal of this experiment was to evaluate whether elevated concentrations of effluent- $\text{NH}_4$  or  $\text{NH}_4$  alone influenced primary production or phytoplankton  $\text{NH}_4$  and  $\text{NO}_3$  uptake and if an effect was observed, to determine the lowest concentration at which it occurred.

### 3.0 Detailed Sampling and Analytical Methods

#### 3.1 Water Column Sampling

At each station, a Seabird Electronics SBE-32 rosette mounted with three 6-L Niskin bottles and fitted with a Seabird SBE-19 plus CTD was lowered over the side. Salinity, temperature and *in vivo* fluorescence (using a Wetlabs fluorometer) were measured continuously from surface to approximately 0.5 m off of the bottom. In addition, light attenuation was assessed using a LiCor PAR sensor mounted on the rosette. A separate measure of light attenuation was made using a 0.3-m diameter Secchi disk. The light attenuation coefficient,  $k$ , was determined by either plotting the natural log of PAR versus depth and using the slope of least-squares regression or, in the case of the Secchi disc, using the equation  $k = 0.4 + 1.09/\text{Secchi depth}$  (Cloern 1991). Water was collected at the surface (<0.5m) using the Niskin bottle samplers. Each Niskin bottle was numbered (1 to 3) with bottles closed sequentially starting at bottle 1. Samples for chemical and biological analyses were collected from assigned bottles using the following sampling order:

Bottle 3: Sample for dissolved inorganic carbon was collected into a 22-ml glass scintillation vial and preserved with 200- $\mu\text{l}$  of 5%w/v  $\text{HgCl}_2$ .

Bottles 1, 2 and 3: Using syringe fitted with a 25-mm Whatman GF/F filter, one sample was collected in a 25ml HDPE scintillation vial for  $\text{NO}_3+\text{NO}_2$ ,  $\text{PO}_4$  and  $\text{Si}(\text{OH})_4$  analyses.

Bottles 1, 2 and 3: Using syringe fitted with a 25-mm Whatman GF/F filter, one 25-ml sample was collected in a 60-ml centrifuge tube for  $\text{NH}_4$  analysis.

Bottles 1, 2 and 3: Using syringe fitted with a 25-mm Whatman GF/F filter, one 25-ml sample was collected in a 60ml centrifuge tube for urea analysis.

Bottles 1, 2 and 3: 500-ml sample was collected into an opaque plastic bottle for *in vitro* chlorophyll-a and particulate organic carbon and nitrogen (POC and PON, respectively) analyses.

Bottle 1: 20-ml sample was collected into a 25-ml plastic scintillation vial for flow cytometry.

Bottle 1: 200-ml sample was collected in a 250-ml glass amber bottle and preserved with acid-Lugols solution for phytoplankton enumeration.

Bottle 2: Two 160-ml clear polycarbonate bottles filled for  $^{13}\text{C}/^{15}\text{N}$  tracer uptake incubations (during 2009 transects only).

Bottle 3: Sample collection by SRWTP (Michael Cook).

### **3.2 Nutrient Analysis**

Samples for  $\text{NO}_3$ ,  $\text{NO}_2$ ,  $\text{PO}_4$ , and  $\text{Si}(\text{OH})_4$  were first filtered through 25-mm GF/F filters using a hand syringe into 20-ml HDPE scintillation vials and frozen until analysis. Before analysis samples were thawed at room temperature for 24-hr to minimize  $\text{Si}(\text{OH})_4$  polymerization effects (MacDonald et al. 1986) and then analyzed using a Bran and Luebbe AutoAnalyzer II (Whitledge et al. 1981 for  $\text{NO}_3$ ,  $\text{NO}_2$  and  $\text{PO}_4$ ; Bran and Luebbe, 1999 for  $\text{Si}(\text{OH})_4$ ). Water samples for  $\text{NH}_4$  analysis, filtered through GF/F filters into 60-ml sterile Falcon tubes were frozen until analysis. Ammonium concentrations were manually determined by the phenol-hypochlorite colorimetric method of Solorzano (1969) using a Hewlett Packard diode array spectrophotometer and 10-cm path length cell. Urea was measured according to Revilla et al. (2005) on 25-ml surface samples, filtered through GF/F filters.

### **3.3 Dissolved Inorganic Carbon**

Dissolved inorganic carbon (DIC) was measured according to Friederich et al. (2002) using a Monterey Bay Research Institute-clone DIC analyzer with acid-sparging and a LiCor nondispersive infra-red detector (Model 6252). DIC concentrations were calculated using the certified reference material prepared at the Scripps Institution of Oceanography (A. Dickson Laboratory).

### **3.4 *In Vitro* Chlorophyll-a, Phaeophytin and Flow Cytometry Analysis**

Extracted chlorophyll-a and phaeophytin was determined on GF/F filters (for all cells  $>0.7\text{-}\mu\text{m}$ ) and 5- $\mu\text{m}$  pore-size Nucleopore filters ( $>5.0\text{-}\mu\text{m}$  cell sized phytoplankton). Filtration volumes were 50 - 100-ml and chosen to ensure sufficient material collection but also to minimize filtration times. Filtration was carried out under a gentle ( $<250\text{-mm}$  Hg) vacuum on a manifold with a Cole-Palmer vacuum pump. Filters were collected and stored frozen in glass culture tubes until analysis within one week of collection. Analysis was performed fluorometrically on acetone extracts according to Arar and Collins (1992) using a Turner Designs Model 10 AU fluorometer calibrated with commercially available chlorophyll-a (Sigma

Chemical). Flow cytometry was assessed using a CytoBuoy flow cytometer (Dubelaar & Gerritzen, 2000).

### **3.5 Primary Production, Phytoplankton Nitrogen Uptake and Particulate Organic Carbon and Nitrogen.**

Carbon and nitrogen uptake were estimated using dual-labeled stable isotope tracer techniques (Legendre and Gosselin, 1996). Surface water was dispensed into two 160-ml clear polycarbonate bottles. One bottle was inoculated with  $^{15}\text{NH}_4\text{Cl}$  and the other with  $\text{K}^{15}\text{NO}_3$  (99 atom %  $^{15}\text{N}$ ) at approximately 10% of anticipated ambient  $\text{NH}_4$  or  $\text{NO}_3$  concentration.  $\text{Na}_2^{13}\text{CO}_3$  was added to each bottle at approximately 10% of ambient DIC concentration. After inoculation, bottles were placed in bay water-cooled incubator tables at 50% surface irradiance (under window screening). Incubations were carried out for 24-hr (river transect samples) or 4-hours (for grow-out/enclosure samples) and were terminated by gentle vacuum filtration onto pre-combusted (450°C for 4 hours) 25 mm GF/F filters. Phytoplankton  $^{13}\text{C}$  and  $^{15}\text{N}$  enrichment were measured on a Europa 20/20 gas chromatograph – mass spectrometer. Transport rates ( $\rho$ , in  $\mu\text{moles L}^{-1} \text{h}^{-1}$  or  $\mu\text{mol L}^{-1} \text{d}^{-1}$ ) and specific uptake ( $V$ , in  $\text{h}^{-1}$ ) were calculated according to Dugdale and Wilkerson (1986) and Legendre and Gosselin (1996).

During the  $\text{NH}_4\text{Cl}$  and effluent addition experiments  $^{14}\text{C}$ -based primary production estimates were made using the JGOFS (1996) method. Samples were dispensed into 160-ml incubation bottles and 6.4  $\mu\text{Ci}$  additions of  $^{14}\text{C}\text{-NaHCO}_3$  were added. Incubation bottles were then placed in baywater cooled incubation tables under ambient light attenuated to 50% of surface PAR for 4-hr. Incubations were terminated under gentle vacuum filtration with particulate collection onto 25-mm GF/F filters. Samples were then acid fumed (with addition of 250- $\mu\text{l}$  10% HCl) for 24-hr, dried and placed in 7-ml scintillation vials. Scintillation cocktail was then added (OptiPhase ‘HighSafe’ 3, Perkin Elmer) and samples were dark acclimated for 24-hr prior to be counted on a Wallac Scintillation counter.

We observed a systematic bias in primary production estimates determined from  $^{13}\text{C}$  and  $^{14}\text{C}$  approaches. It is unclear what the reason is for the observed bias which resulted in substantially higher  $^{13}\text{C}$ -based primary production compared to  $^{14}\text{C}$ -based primary production. Some of the bias may be the result of nonliving carbonate in the POC (C. Kendall, pers comm.) which would explain the observations as  $^{13}\text{C}$ -based primary production relies on POC determinations whereas  $^{14}\text{C}$  primary production is dependent on DIC concentrations and does not rely on estimates of POC. We present results of both  $^{13}\text{C}$  and  $^{14}\text{C}$  here focusing analysis on trends and caution against comparisons of absolute values reported for  $^{13}\text{C}$ -primary production between this dataset and those previously reported for the Sacramento River.

## **4.0 Results**

### ***4.1 River Characterization***

*July 2008 (WBD08-1)*

Temperature varied little ( $\pm 1.5^\circ \text{C}$ ) between I-80 (21.6° C) and Isleton (22.5 °C) and EC remained constant between all stations (Table 4). Nitrate, nitrite ( $\text{NO}_2$ ),  $\text{NH}_4$ , urea,  $\text{PO}_4$  and silicate ( $\text{Si}(\text{OH})_4$ ) showed small fluctuations between stations from I-80 to GRC (Table 4, Fig. 2,

Fig. 3) but then constituents increased downstream of RM-44. Nitrate increased downstream of HOD, along with  $\text{PO}_4$ ; maximum values for  $\text{NO}_3$  and  $\text{PO}_4$  were observed at ISL (Table 4). Silicate remained consistently high ( $> 290 \mu\text{mol L}^{-1}$ ) along the sampling transect. Ammonium concentrations increased at RM-44, reaching a maximum at HOD of  $25.07 \mu\text{mol L}^{-1}$  (Table 4, Fig. 3B). The SRWTP discharge is located between GRC and RM-44.

Extracted chlorophyll-a in cells  $>0.7\text{-}\mu\text{m}$  diameter was  $4.6 \mu\text{g L}^{-1}$  at I80, and declined downstream from OAK. At HOD, chlorophyll-a concentrations ( $1.9 \mu\text{g L}^{-1}$ ) were less than 50% of values observed at I80 (Table 5). The chlorophyll-a concentrations for each of the two size fractions ( $>0.7$  and  $>5.0\text{-}\mu\text{m}$ ) suggested that there was a larger chlorophyll-a contribution (60 to 79%, mean of 70%) by cells  $>5\text{-}\mu\text{m}$  than smaller cells. These results were consistent with those measured by flow cytometry (Fig. 4A) which showed that most fluorescent particles ranged in size between 5 and  $50\text{-}\mu\text{m}$  (fluorescent particle abundance was  $>2$ -fold higher than the abundance in the 1 to  $5\text{-}\mu\text{m}$  size category, average for  $1\text{-}5\text{-}\mu\text{m}$   $7 \times 10^2 \text{ cells ml}^{-1}$  versus  $2.2 \times 10^3 \text{ cells ml}^{-1}$  for  $5$  to  $50\text{-}\mu\text{m}$ ). Both size classes showed the same trend, with declining particle number between OAK and HOD consistent with the trends observed for chlorophyll-a (Table 5). Samples for particulate organic carbon (POC) and nitrogen (PON) were not measured during this transect (Table 6). Secchi depth decreased moving downstream between OAK and ISL from 1.4 to 1-m (Fig. 2A, Table 6).

*November 2008 (WBD08-2)*

Changes in temperature between I80 ( $13.9^\circ \text{C}$  most northern) and ISL ( $14.7^\circ \text{C}$  most southern) were relatively small. Electrical conductivity increased downstream ranging from 181.9 (at GRC) to  $233.0 \mu\text{S}$  (at RM-44) (Table 7). Nitrate was relatively constant ( $12 \mu\text{mol L}^{-1}$  to  $13 \mu\text{mol L}^{-1}$ ) along the transect from I80 to CRS, but increased ca. 2-fold at ISL ( $23.4 \mu\text{mol L}^{-1}$ ) (Fig. 3A, Table 7). Phosphate increased at RM-44 and remained elevated at ISL. Similar to July 2008,  $\text{Si(OH)}_4$  remained consistently high ( $> 300 \mu\text{mol L}^{-1}$ ) along the transect (Fig. 2B, Table 7). Ammonium was elevated at I80 ( $7.73 \mu\text{mol NH}_4 \text{ L}^{-1}$ ) and decreased to GRC, but then sharply increased to a transect maximum concentration at RM-44 ( $70.82 \mu\text{mol NH}_4 \text{ L}^{-1}$ ). Ammonium declined throughout the rest of the transect but remained elevated ( $>35 \mu\text{M}$ ) compared to the upstream stations (I80, OAK, and GRC) southward to ISL (Fig. 3B, Table 7). Extracted  $>0.7\text{-}\mu\text{m}$  chlorophyll-a ranged from  $3.3 \mu\text{g L}^{-1}$  at I80 and decreased regularly southward toward ISL ( $0.6 \mu\text{g L}^{-1}$ ) (Fig. 4B, Table 8). Chlorophyll-a contained in cells  $>5\text{-}\mu\text{m}$  in diameter also decreased from north to south (Fig. 4B, Table 8). Overall, cells  $>5\text{-}\mu\text{m}$  in diameter contributed between 76 and 99% of total chlorophyll-a, (averaging 85% over the whole transect). Flow cytometry results showed a pattern similar to chlorophyll-a with a declining trend from north to south (Fig. 4B); the highest fluorescent particle counts were observed at I80 ( $1.58 \times 10^6 \text{ cells L}^{-1}$ ) and minimum values were measured at ISL (Table 8).

Particulate organic carbon (POC) ranged between  $36 \mu\text{mol L}^{-1}$  and  $97 \mu\text{mol L}^{-1}$  across all stations, and generally mirrored the decreasing chlorophyll-a trends. POC did increase from  $38 \mu\text{mol L}^{-1}$  at GRC to  $97 \mu\text{mol L}^{-1}$  at RM-44. This increase was inconsistent with chlorophyll-a suggesting that POC other than phytoplankton may have contributed to the POC pool at that station. Particulate organic nitrogen (PON) was low throughout the transect, ranging between 1 and  $4 \mu\text{mol L}^{-1}$ . Daily primary production and phytoplankton nitrogen uptake rates were low ( $<0.3 \mu\text{mol L}^{-1}$  for C) throughout the transect (Fig. 6, Table 9). Secchi depth increased from I80

to ISL in November (from 0.9 to 1.7-m) indicating an increase in photic zone depth (Fig. 2A, Table 9)

#### *March 2009 (WBD09-1)*

Electrical conductivity and temperature did not vary appreciably between I80 and ISL (ca. 100  $\mu\text{S}$  and ca. 11.4°C for EC and temperature, respectively); EC did increase at RIO to 144  $\mu\text{S}$  (Table 10). Nitrate,  $\text{NO}_2$ ,  $\text{Si(OH)}_4$ , and urea showed little fluctuation between I80 and ISL (Table 10); while  $\text{NH}_4$ , which was low at I80 (1.0  $\mu\text{M}$ ) increased at RM-44 (10.09  $\mu\text{mol L}^{-1}$ ) and remained elevated ( $>10 \mu\text{mol L}^{-1}$ ) to ISL before decreasing to 6.4  $\mu\text{mol L}^{-1}$  at RIO (Fig. 3B, Table 10). Nitrate and  $\text{NO}_2$  increased between ISL and RIO (Fig. 3A, Fig. 3D). Phosphate concentrations increased at RM-44 to 1.94  $\mu\text{mol L}^{-1}$  (Fig. 2C, Table 10). Total chlorophyll-a was 1.9  $\mu\text{g L}^{-1}$  at I80 and reached a maximum value of 3.8  $\mu\text{g L}^{-1}$  immediately downstream at OAK and then decreased downstream to RIO (Table 11, Fig. 5). Chlorophyll-a in cells  $>5\text{-}\mu\text{m}$  in diameter ranged between 1.0  $\mu\text{g L}^{-1}$  at RIO and 2.2  $\mu\text{g L}^{-1}$  at OAK and GRC (Table 11) and chlorophyll-a in cells  $>5\text{-}\mu\text{m}$  contributed on average 62% to the total chlorophyll-a (Table 11). Flow cytometry data generally showed decreasing trends from I80 to RIO for fluorescent particle abundance with the highest numbers at I80 ( $1.1 \times 10^6$  particles  $\text{mL}^{-1}$ ) and minimum values ( $0.7 \times 10^6$  particles  $\text{mL}^{-1}$ ) measured at RIO (Table 10). Fluorescent particles between 5 to 50- $\mu\text{m}$  in size were roughly 2-fold more abundant than smaller particles (average for size range 1 to 5- $\mu\text{m}$  was  $3.2 \times 10^2$  particles  $\text{mL}^{-1}$  and  $6.6 \times 10^2$  particles  $\text{mL}^{-1}$  for 5 to 50- $\mu\text{m}$ ) (Fig. 5A).

POC values varied between 108 and 152  $\mu\text{mol C L}^{-1}$  and PON values ranged between 6 and 12  $\mu\text{mol N L}^{-1}$  (Table 11). Secchi depth remained relatively constant ranging between 0.4 and 0.5-m (Fig. 2A, Table 12). Primary production rates varied between 6.48 and 11.52  $\mu\text{mol L}^{-1} \text{d}^{-1}$  across all stations (Fig. 6B, Table 12), and phytoplankton  $\text{NH}_4$  uptake rates ranged from 0.53 to 0.98  $\mu\text{mol L}^{-1} \text{d}^{-1}$  with the peak value observed at RM-44. Phytoplankton  $\text{NO}_3$  uptake rates were greatest at the 3 upstream stations, I80, OAK, GRC, ranging from 0.34 to 0.41  $\mu\text{mol L}^{-1} \text{d}^{-1}$  above SRWTP and then dropped to  $\leq 0.07 \mu\text{mol L}^{-1} \text{d}^{-1}$  at all southward stations to RIO (Fig. 6B, Table 12) reflecting the increasing  $\text{NH}_4$  concentrations moving in the downstream direction.

#### *April 2009 (WBD09-2)*

Temperature varied between 14.4 and 15.7°C and EC varied between 104 and 140  $\mu\text{S}$  between I80 and RIO; EC values did increase substantially at RIO (192.7  $\mu\text{S}$ ) (Table 13). Nitrate,  $\text{NO}_2$ ,  $\text{Si(OH)}_4$  and urea showed small fluctuations between I80 and ISL (Fig. 2C, Fig. 3A,C,D, Table 13);  $\text{NO}_3$  increased from ISL to RIO from 8.50 to 24.60  $\mu\text{mol L}^{-1}$  (ca. 3-fold increase). At HOD  $\text{NH}_4$  and  $\text{PO}_4$  increased (Fig. 2C, Fig. 3B, Table 13);  $\text{NH}_4$  increased from  $<1 \mu\text{mol L}^{-1}$  up to 21  $\mu\text{mol L}^{-1}$  while  $\text{PO}_4$  increased from 0.6  $\mu\text{mol L}^{-1}$  to 2.4  $\mu\text{mol L}^{-1}$ , and remained elevated until RIO (Table 13). Total chlorophyll-a was relatively high between I80 and GRC (averaging 5.72  $\mu\text{g L}^{-1}$ ) and then declined to 4.7  $\mu\text{g L}^{-1}$ . Downstream of RM-44 the values were in the same range as in March 2009. Chlorophyll-a in cells  $>5\text{-}\mu\text{m}$  contributed on average 76% to the total chlorophyll-a over the entire transect. Higher chlorophyll-a concentrations on the April 2009 cruise matched the higher observed concentrations of fluorescent particles (Table 14) (average for 1 to 5 $\mu\text{m}$  was  $3.4 \times 10^3$  cells  $\text{mL}^{-1}$  and  $1.1 \times 10^3$  cells  $\text{mL}^{-1}$  for 5 to 50 $\mu\text{m}$ ) (Fig. 5B). In contrast to the other transects the smaller fluorescent particle size class was more abundant than the large size class.

POC values varied from 45  $\mu\text{mol L}^{-1}$  to 87  $\mu\text{mol L}^{-1}$  while PON ranged between 3 and 9  $\mu\text{mol L}^{-1}$  (Table 14). Both POC and PON generally trended downward from northern to southern station following the pattern observed for chlorophyll-a. Secchi depth increased moving downstream from I80 to ISL (0.8-m to 1.8-m) and then decreased to 0.6-m at RIO (Table 15). Primary production ranged between 3.1 and 12.0  $\mu\text{mol L}^{-1} \text{d}^{-1}$  across all stations, decreasing from I80 to ISL (Fig. 6C, Table 15). Phytoplankton  $\text{NH}_4$  uptake rates ranged between 0.47 and 1.19  $\mu\text{mol L}^{-1} \text{d}^{-1}$  along the transect, with the maximum value at RM-44; Phytoplankton  $\text{NO}_3$  rates were highest at the 3 northernmost stations (I80, OAK, and GRC) ranging between 1.70 and 2.26  $\mu\text{mol L}^{-1} \text{d}^{-1}$ . Below RM-44  $\text{NO}_3$  uptake decreased to  $<0.03 \mu\text{mol L}^{-1} \text{d}^{-1}$  to RIO (Fig. 6C, Table 15).

*May 2009 (WBD09-3)*

Temperature ( $16.2^\circ\text{C} \pm 0.7$ ) varied little between I80 and ISL while EC varied by ca. 25% ( $104 \pm 25 \mu\text{S}$ ) between these stations, increasing (to 125.7  $\mu\text{S}$ ) at RIO (Table 16). Nitrate,  $\text{NO}_2$ ,  $\text{Si(OH)}_4$  and urea showed little change between I80 and ISL (Fig. 2B, Fig. 3A,C,D, Table 16); with small increases in concentrations observed at RIO (particularly for  $\text{NO}_3$ ,  $\text{NO}_2$ , and urea) (Table 16). At RM-44  $\text{NH}_4$  and  $\text{PO}_4$  increased, in the case of  $\text{NH}_4$  the increase was roughly 8-fold (from ca. 1  $\mu\text{mol L}^{-1}$  up to 11.1  $\mu\text{mol L}^{-1}$ ). Phosphate increased from 0.9  $\mu\text{mol L}^{-1}$  to 1.4  $\mu\text{mol L}^{-1}$ , and remained elevated to ISL with another increase in concentrations at RIO (Table 16).

Total and  $>5\text{-}\mu\text{m}$  chlorophyll-a showed minor changes in concentration between I80 and ISL (4.5 to 6.2  $\mu\text{g L}^{-1}$ ), and then decreased significantly at RIO (2.26  $\mu\text{g L}^{-1}$  and 0.79  $\mu\text{g L}^{-1}$  for total and  $>5\text{-}\mu\text{m}$  fractions, respectively) (Fig. 5C, Table 17). The  $>5\text{-}\mu\text{m}$  size fraction made up on average, 69% of the total chlorophyll-a in the water column, with maxima at OAK (89%) and a gradual decrease towards RIO (35%). Both size classes of fluorescent particles showed a decreasing trend that was not reflected in the extracted chlorophyll-a analysis. Fluorescent particles counts were in the range of 4.1 to 9.4  $\times 10^2 \text{ mL}^{-1}$  (average 6.75  $\times 10^2 \text{ mL}^{-1}$ ) for particles 1 to 5- $\mu\text{m}$  and 8.4 to 15.5  $\times 10^2 \text{ particles mL}^{-1}$  (average 11.6  $\times 10^2 \text{ particles mL}^{-1}$ ) for particles 5 to 50- $\mu\text{m}$ . The highest fluorescent particle counts were observed at OAK ( $2.2 \times 10^6 \text{ particles L}^{-1}$ ) while the minimum values ( $1.3 \times 10^6 \text{ particles L}^{-1}$ ) were measured downstream at RIO (Fig. 5C, Table 17).

POC and PON values showed relatively large differences between stations (POC ranged between 56 and 180  $\mu\text{mol L}^{-1}$ ); PON values varied between 6 and 17  $\mu\text{mol L}^{-1}$  across the eight stations (Table 17). There were no discernable trends in either parameter except for ISL where maximal values for both POC (180  $\mu\text{mol L}^{-1}$ ) and PON (17  $\mu\text{mol L}^{-1}$ ) were observed and were associated with an increase in chlorophyll-a (Table 17). Secchi depth remained relatively unchanged between I80 and ISL (0.4-m to 0.6-m) and then increased to 0.7-m at RIO (Table 18). Primary production ranged between 5.7 and 12.0  $\mu\text{mol L}^{-1} \text{d}^{-1}$  along the transect, with no obvious trends along from north to south. Phytoplankton  $\text{NH}_4$  uptake was lowest at I80, OAK and GRC and increased at RM-44 and remained high downstream (Table 18). Phytoplankton  $\text{NO}_3$  uptake rates were greatest at the 3 northernmost stations above RM-44 (I80, OAK, GRC) ranging between 0.48 and 1.13  $\mu\text{mol L}^{-1} \text{d}^{-1}$ , corresponding to where  $\text{NH}_4$  concentrations were low (to just above detection limits). Phytoplankton  $\text{NO}_3$  uptake rates were  $<0.06 \mu\text{mol L}^{-1} \text{d}^{-1}$  for the rest of the transect (Fig. 6D, Table 18).

### *Seasonal Comparisons of River Transects*

Comparisons of river parameters between transect dates are shown in Figures 2, 3, 4, 5 and 6. Nitrate concentrations were lowest in July 2008 and April 2009, whereas during November 2008, March 2009 and May 2009,  $\text{NO}_3$  concentrations were similar (ca.  $10 \mu\text{mol L}^{-1}$  to  $13 \mu\text{mol L}^{-1}$  at I80 (Fig. 3A). This difference may have been due in part to Sacramento River flow which was relatively low (13,033 and 12,035 cfs for July 2008 and April 2009, respectively). During the other two cruises in 2009, Sacramento River flow was >2-fold higher (Table 2). Sacramento River flow in November 2008 was similar to July 2008 and April 2009 but  $\text{NO}_3$  concentrations were more similar to the high flow periods in 2009.  $\text{NH}_4$  concentrations were always low ca.  $\leq 1.0 \mu\text{mol L}^{-1}$  upstream of RM-44 and generally increased at RM-44. However, the maximal  $\text{NH}_4$  concentrations were not always found at RM-44. The November 2008  $\text{NH}_4$  concentrations were substantially higher (up to 4-fold) than  $\text{NH}_4$  concentrations on any other transect (Fig. 3B). Urea concentrations showed some spatial variation but no consistent spatial patterns across cruises (Fig. 3C). Urea concentrations were lower than either  $\text{NO}_3$  or  $\text{NH}_4$ , ranging between  $<0.1 \mu\text{mol L}^{-1}$  and  $1.3 \mu\text{mol L}^{-1}$  (Fig. 3C).  $\text{NO}_2$  concentrations were also low throughout all transects but showed an increase in concentrations downstream of RM-44 (Fig. 3D). During March 2009  $\text{NO}_2$  concentrations were also elevated (approaching  $0.6 \mu\text{mol L}^{-1}$ ) at I80.

Nitrite concentrations were low along all transects relative to both  $\text{NO}_3$  and  $\text{NH}_4$  (below  $2 \mu\text{mol L}^{-1}$ ) however, the spatial patterns in  $\text{NO}_2$  concentration may provide some indication of microbial processes likely to play a role in the magnitude and distribution of DIN in the Sacramento River. Figure 7 (April 2009) shows the typical pattern for  $\text{NO}_3$ ,  $\text{NH}_4$  and  $\text{NO}_2$  along the eight station transect (note, for all other transect graphs and tables  $\text{NO}_2$  is reported along with  $\text{NO}_3$  as “ $\text{NO}_3 + \text{NO}_2$ ”). Unlike  $\text{NH}_4$ , which increased rapidly downstream of RM-44,  $\text{NO}_2$  concentrations tended to gradually increase downstream of RM-44. This suggests that SRWTP was not a large source of  $\text{NO}_2$ , however, the oxidation of  $\text{NH}_4$  to  $\text{NO}_2$  (i.e. the first step in the sequential oxidation of  $\text{NH}_4$  to  $\text{NO}_3$ , nitrification) is likely the underlying mechanism responsible for at least some of the increase in  $\text{NO}_2$ . In addition,  $\text{NO}_3$  concentrations steadily increased downstream of the SRWTP. Again, the gradual increase in  $\text{NO}_3$  does not suggest that SRWTP is a major source of  $\text{NO}_3$ , but rather nitrification within the river may be important in the conversion of  $\text{NH}_4$  to  $\text{NO}_3$ . Stable isotope analysis of  $\text{NO}_3$  and  $\text{NH}_4$  within the Sacramento River along this region also indicates the potential for substantial rates of nitrification (C. Kendall, pers comm.).

Secchi depth was lower during March 2009 and May 2009 compared to July 2008, November 2008 and April 2008 (Fig. 2A). This difference is likely due to the differences in Sacramento River flow with higher flows (ca. >25,000 cfs) resulting in lower Secchi depths (ca. 0.4-m) (Fig. 4A). Silicate concentrations were all high relative to the other inorganic nutrients measured during these transects, however, July 2008 did show lower  $\text{Si}(\text{OH})_4$  concentrations at all stations compared to the other transects (Fig. 2B).  $\text{PO}_4$  concentrations all increased at RM-44 and generally continued to increase along transects moving southward. The exception to this trend was during November 2008, when  $\text{PO}_4$  concentrations were all high relative to the other dates when these stations were visited (Fig. 2C).

Primary production was low in November 2008, compared to primary production estimates made during the three cruises in 2009 (Table 9, Fig. 6). During March and May, when Sacramento River flow was high (ca. 25,000 cfs, Table 2) primary production estimates did not show a discernable trend along the north to south transect (Fig. 6). In contrast, during April 2009 when Sacramento River flow was low (12,000 cfs) primary production estimates revealed a steady decline in rates from north to south, consistent with the patterns observed for chlorophyll-a (Table 15, Fig. 6).

#### ***4.2 River Grow-Out Experiments***

##### *July 2008*

During July 2008 grow-out experiments were carried out for 216-hr using un-amended water collected at GRC and RM-44. Initial conditions of both stations (Table 19) were similar for inorganic nutrients,  $\text{NO}_3$ ,  $\text{PO}_4$ ,  $\text{Si}(\text{OH})_4$ , and for chlorophyll-a. Initial  $\text{NH}_4$  concentrations at GRC were  $0.4 \mu\text{mol L}^{-1}$  and  $9.06 \mu\text{mol L}^{-1}$  at RM-44. By 96-hr,  $\text{NO}_3$  was exhausted in both enclosures and  $\text{NH}_4$  and  $\text{PO}_4$  were  $<1 \mu\text{mol L}^{-1}$ . Final chlorophyll-a concentrations were  $14.7 \mu\text{g L}^{-1}$  at RM-44 versus  $1.2 \mu\text{g L}^{-1}$  at GRC. The low initial concentrations of all inorganic nutrients in the GRC water resulted in nutrient limitation early in the grow-out experiments at GRC, resulting in lower overall chlorophyll-a GRC enclosures compared to RM-44. The larger pool of DIN, due to more available  $\text{NH}_4$  at RM-44, was able to support a substantial gain in chlorophyll-a.

##### *November 2008*

Similar to July 2008, 96-hr grow-out experiments were carried out on un-amended natural assemblages of river phytoplankton from GRC and RM-44. Initial inorganic nutrients at both stations (Table 20) were similar for  $\text{NO}_3$  and  $\text{Si}(\text{OH})_4$ , but  $\text{PO}_4$  and  $\text{NH}_4$  were elevated at RM-44 ( $71.87 \mu\text{mol L}^{-1}$  compared to GRC  $3.4 \mu\text{mol L}^{-1}$ ). Initial chlorophyll-a concentrations were low, ca.  $1 \mu\text{g L}^{-1}$ . After 96-hrs of incubation RM-44 chlorophyll-a concentrations increased to  $11.4 \mu\text{g L}^{-1}$  based mainly on  $\text{NH}_4$  consumption of  $12.5 \mu\text{mol L}^{-1}$ . The GRC grow-out chlorophyll-a increased to  $16.7 \mu\text{g L}^{-1}$  based mainly on  $\text{NO}_3$  drawdown of  $9.2 \mu\text{mol L}^{-1}$ .

##### *March 2009*

Grow-out experiments during 2009 were different than those performed in 2008 in that additions of inorganic nitrogen were made (both as  $\text{NO}_3$  and  $\text{NH}_4$ ) to GRC enclosures so that both GRC and RM-44 grow-outs started with roughly the same ambient DIN (Table 21). Grow-outs were monitored daily for 96-hr. Nutrient amended samples were designated either as GRC +  $\text{NO}_3$  or GRC +  $\text{NH}_4$  for GRC grow-outs with additions of  $\text{NO}_3$  or  $\text{NH}_4$ , respectively. We have reported nutrient and chlorophyll-a after the 96-hr incubation period under ambient temperature and 50% surface solar irradiance.

Nutrient concentrations in un-amended (i.e. no DIN additions) GRC and RM-44 grow-outs were similar (Table 21) for  $\text{NO}_3$ ,  $\text{Si}(\text{OH})_4$ , chlorophyll-a and  $\text{PO}_4$ . In contrast,  $\text{NH}_4$  concentrations were 12-fold higher at RM-44 compared to GRC ( $12.47$  versus  $1.02 \mu\text{mol L}^{-1}$ ). By 96-hr,  $\text{NO}_3$  and  $\text{PO}_4$  were exhausted in the un-amended GRC grow-outs, resulting in a total

chlorophyll-a yield of  $12.6 \mu\text{g L}^{-1}$ . Un-amended grow-outs from RM-44 showed roughly 33% more chlorophyll-a ( $18.83 \mu\text{g L}^{-1}$ ) compared to the un-amended GRC grow-outs. Larger phytoplankton cells ( $> 5\text{-}\mu\text{m}$ ) made up about 70% of the chlorophyll-a biomass in GRC and 60% in RM-44. RM-44 phytoplankton growth appeared to be driven more by  $\text{NH}_4$  drawdown; while  $\text{NO}_3$  drawdown was more significant in un-amended GRC grow-outs (Table 21).

In the amended grow-outs, the GRC+ $\text{NH}_4$  treatment behaved similarly to un-amended RM-44, accumulating similar concentrations of chlorophyll-a over the 96-hr period, ( $17.0 \mu\text{g L}^{-1}$ ) and utilizing  $\text{NH}_4$  rather than  $\text{NO}_3$  in support of that phytoplankton growth. The GRC +  $\text{NO}_3$  treatment accumulated the lowest chlorophyll-a concentrations ( $10.9 \mu\text{g L}^{-1}$ ) during the 96-hr growth period and behaved mostly similarly to the un-amended GRC river water.

*May 2009*

Both un-amended and DIN amended grow-out experiments were also carried out in May 2009 (Table 22). Un-amended grow-outs from GRC and RM-44 were similar in initial concentrations of  $\text{NO}_3$ ,  $\text{Si(OH)}_4$ , and chlorophyll-a (Table 22) while initial  $\text{NH}_4$  was 7-fold higher at RM-44 compared to GRC ( $12.47$  vs.  $1.02 \mu\text{mol L}^{-1}$ ) and  $\text{PO}_4$  was 2-fold higher at RM-44 compared to GRC ( $1.24$  versus  $0.77 \mu\text{mol L}^{-1}$ ). By 96-hr,  $\text{NO}_3$  and  $\text{PO}_4$  were exhausted in the un-amended GRC grow-out resulting in chlorophyll-a concentrations of  $9.0 \mu\text{g L}^{-1}$ . Chlorophyll-a concentrations in un-amended RM-44 grow-outs were roughly 25% higher than those at GRC ( $13.8 \mu\text{g L}^{-1}$ ). By 96-hr RM-44 grow-outs showed both  $\text{NO}_3$  and  $\text{NH}_4$  drawdown, with both constituents approaching 0 (Table 22). Interestingly, unlike previous grow-out experiments there was significant silicate drawdown observed in the RM-44 grow-out.

Amended grow-out treatments behaved similarly to each other, with accumulations of chlorophyll-a of  $13 \mu\text{g L}^{-1}$  over 96-hr. Both treatments used both  $\text{NO}_3$  and  $\text{NH}_4$  to support growth. Silicate drawdown was noted more significantly in these experiments than in the previous months.

#### ***4.3 River Water Aging Experiment***

20-L cubitainers were collected on July 2008 at GRC and RM-44 and incubated in the dark at  $21^\circ\text{C}$  for 8 weeks (Table 23). Initial  $\text{NO}_3 + \text{NO}_2$  and  $\text{Si(OH)}_4$  concentrations were similar between the two water samples ( $0.64 \mu\text{mol N L}^{-1}$  and  $0.47 \mu\text{mol N L}^{-1}$  and  $311 \mu\text{mol Si(OH)}_4 \text{ L}^{-1}$  and  $295 \mu\text{mol Si(OH)}_4 \text{ L}^{-1}$  respectively). Initial  $\text{PO}_4$  concentration in RM-44 water was much higher (3.8-fold higher) than  $\text{PO}_4$  in GRC water, as was the initial  $\text{NH}_4$  concentration that was  $>20$ -fold higher in RM-44 water ( $17.5 \mu\text{mol L}^{-1}$ ) compared to GRC ( $0.8 \mu\text{mol L}^{-1}$ ). Inorganic nutrient concentrations measured weekly in the two cubitainers showed a decrease in  $\text{NH}_4$  and an increase in  $\text{NO}_3 + \text{NO}_2$  over time. This was well demonstrated for RM-44 where initial  $\text{NH}_4$  was higher ( $17.5 \mu\text{mol L}^{-1}$ ) and all converted to  $\text{NO}_3$  ( $\text{NO}_3 = 17.6 \mu\text{mol L}^{-1}$ ) after 2 weeks. The overall change in  $\text{NO}_3 + \text{NO}_2$  and  $\text{NH}_4$  in the GRC cubitainer was less clear. After one week there was little change in any of the inorganic nutrients monitored in either cubitainer (GRC or RM-44). The initiation of the decrease in  $\text{NH}_4$  and conversion to  $\text{NO}_3 + \text{NO}_2$  occurred after two weeks and had reached completion (i.e. near complete conversion of all available  $\text{NH}_4$  to  $\text{NO}_3 + \text{NO}_2$ ) after 3 weeks. Phosphate concentrations did not vary substantially from the initial concentrations suggesting that  $\text{PO}_4$  was not required or produced (e.g. via DOM degradation) as a result of this

nitrogen transformation. The same was observed for  $\text{Si}(\text{OH})_4$  that remained high throughout the 8 weeks.

#### ***4.4 $\text{NH}_4\text{Cl}$ Addition Experiment***

During April 2009 (WBD09-2)  $\text{NH}_4$  was added to river water from GRC (upstream of the SRWTP with low  $\text{NH}_4$  concentrations) and the effect on primary production and phytoplankton nitrogen uptake was compared to un-amended water from GRC and RM-44 (RM-44 is immediately downstream of SRWTP discharge) (Table 24). Interestingly both GRC and RM-44 had low initial  $\text{NH}_4$  concentrations;  $0.35 \mu\text{mol L}^{-1}$  at GRC and  $0.87 \mu\text{mol L}^{-1}$  in RM-44 water, atypical for RM-44. Three concentration additions of  $\text{NH}_4\text{Cl}$  were made to the GRC water:  $+1 \mu\text{mol NH}_4 \text{L}^{-1}$ ,  $+4 \text{NH}_4 \mu\text{mol L}^{-1}$ , and  $+50 \text{NH}_4 \mu\text{mol L}^{-1}$ . Primary production was lowest at RM-44 as was chlorophyll-a (Table 14) ( $0.9 \mu\text{mol C L}^{-1} \text{h}^{-1}$ , Table 24). In experiments using GRC water there was little effect on primary production with  $\text{NH}_4\text{Cl}$  additions (Table 24) up to  $4 \mu\text{mol L}^{-1}$ . The small decline in primary production ( $0.1 \mu\text{mol C L}^{-1} \text{h}^{-1}$ , ca. 8% of primary production at GRC) between un-amended GRC and GRC  $+50 \mu\text{mol NH}_4 \text{L}^{-1}$  observed in  $^{13}\text{C}$ -based primary production was significant (t-test,  $P = 0.02$ ) but similar declines were not evident in the  $^{14}\text{C}$ -based estimates. Phytoplankton  $\text{NH}_4$  uptake showed a small decrease with additions of  $\text{NH}_4$  ( $0.013 \mu\text{mol L}^{-1} \text{h}^{-1}$ ). The strongest effect of added  $\text{NH}_4\text{Cl}$  was observed in estimates of phytoplankton  $\text{NO}_3$  uptake, which was reduced in all the  $\text{NH}_4$  addition treatments (from  $0.028 \mu\text{mol L}^{-1} \text{h}^{-1}$  to  $0 \mu\text{mol L}^{-1} \text{h}^{-1}$  with the  $+50 \mu\text{mol NH}_4 \text{L}^{-1}$  addition. The total N uptake declined steadily with  $\text{NH}_4$  additions from  $0.088 \mu\text{mol L}^{-1} \text{h}^{-1}$  to  $0.050 \mu\text{mol L}^{-1} \text{h}^{-1}$  at the  $+50 \mu\text{mol L}^{-1}$  addition, a decrease of 43% over GRC  $+1 \mu\text{mol L}^{-1}$ . This experiment unfortunately started with water that had uncharacteristic initial nutrient conditions; lower  $\text{NO}_3$  at GRC and lower  $\text{NH}_4$  at RM-44 than typically measured.

#### ***4.5 Effluent Addition Experiments***

An experiment similar to that described by MacIsaac et al. (1979) was carried out in May 2009 to evaluate the impact of SRWTP effluent on primary production and phytoplankton N uptake. Primary productivity and phytoplankton nitrogen uptake were estimated in bottles filled with water from GRC and serial additions of SRWTP effluent- $\text{NH}_4$  or equivalent concentrations of  $\text{NH}_4\text{Cl}$ . Ambient  $\text{NH}_4$  concentrations were  $1.65 \mu\text{mol L}^{-1}$  and  $31.71 \mu\text{mol L}^{-1}$  at GRC and RM-44, respectively.  $\text{NH}_4$  concentrations at GRC were well below the  $4 \mu\text{mol L}^{-1}$  total  $\text{NO}_3$  uptake inhibition threshold described by Dugdale et al (2007); but ca.  $1 \mu\text{mol L}^{-1}$  ambient  $\text{NH}_4$  may have had some inhibitory effect on measured phytoplankton  $\text{NO}_3$  uptake at GRC during the experiment. The initial  $\text{NO}_3$  concentration at GRC was  $2.16 \mu\text{mol L}^{-1}$  (versus  $2.71 \mu\text{mol L}^{-1}$  at RM-44).

The  $\text{NH}_4$  concentration in the SRWTP composite sample was  $1933 \mu\text{mol L}^{-1}$ . This was added to GRC water as a dilution series along with a comparable set of bottles using a dilution series of  $\text{NH}_4\text{Cl}$ . The  $\text{NH}_4$  addition series ranged from  $0.40 \mu\text{mol N L}^{-1}$  to  $100 \mu\text{mol N L}^{-1}$ , representing effluent dilutions of 1:20 to 1:5000 (Table 25, Table 27, Table 28). The SRWTP must maintain a dilution of 1:14; based on the effluent composite  $\text{NH}_4$  concentration, the 1:14 dilution would result in river concentrations of ca.  $143 \mu\text{mol L}^{-1}$  in the immediate discharge receiving waters. It should be noted that the river concentrations that were observed during the transects completed in 2008 and 2009 never reached more than 50% of this theoretical value (the highest recoded  $\text{NH}_4$  value during all transects was ca.  $70 \mu\text{mol L}^{-1}$  at RM-44, recorded during

November 2008). As with the  $\text{NH}_4\text{Cl}$  addition experiment described in Section 4.4, the relationship between primary production and  $\text{NH}_4$  concentration was investigated using both  $^{14}\text{C}\text{-HCO}_3$  and  $^{13}\text{C}\text{-HCO}_3$  tracers.

$^{14}\text{C}$ -Primary production under ambient  $\text{NH}_4$  concentrations at RM-44 was also measured for comparison with rates for un-amended GRC water and was lower- by almost a factor of 2.  $^{14}\text{C}$ -primary production at GRC varied between 1.00 to 1.33  $\mu\text{mol L}^{-1} \text{h}^{-1}$  across the  $\text{NH}_4$  addition series with the highest primary production rates reported at  $\text{NH}_4\text{Cl}$  additions of +0.50 and +16  $\mu\text{mol NH}_4 \text{L}^{-1}$  (Table 26).  $^{14}\text{C}$ -primary production rates in bottles with additions of SRWTP effluent varied between 0.61 and 1.20  $\mu\text{mol C L}^{-1} \text{h}^{-1}$  with the highest primary production values measured at +4 and +16  $\mu\text{mol effluent-NH}_4 \text{L}^{-1}$ . The lowest  $^{14}\text{C}$ -primary production estimates were found at +32 and +100  $\mu\text{mol effluent-NH}_4 \text{L}^{-1} \text{h}^{-1}$  and the difference between “GRC + 0” effluent- $\text{NH}_4$  versus “GRC+100” effluent  $\text{NH}_4$  was 0.35  $\mu\text{mol C L}^{-1} \text{h}^{-1}$ , equivalent to a 36% decline in primary production.

Primary production estimates using  $^{13}\text{C}$  were higher than those reported using  $^{14}\text{C}$  (see Section 3.5) but showed similar trends. Treatments with additions of  $\text{NH}_4\text{Cl}$  resulted in  $^{13}\text{C}$ -primary production values that ranged between 1.49 and 1.74  $\mu\text{mol L}^{-1} \text{h}^{-1}$  with no discernable trends with increasing additions of  $\text{NH}_4\text{Cl}$  (Table 27).  $^{13}\text{C}$ -Primary production in treatments with wastewater effluent- $\text{NH}_4$  additions showed declining trends at wastewater effluent- $\text{NH}_4 > 8 \mu\text{mol NH}_4 \text{L}^{-1}$ . At effluent concentrations  $< 8 \mu\text{mol NH}_4 \text{L}^{-1}$   $^{13}\text{C}$ -primary production ranged between 1.64 and 1.83  $\mu\text{mol L}^{-1} \text{h}^{-1}$ . At effluent- $\text{NH}_4$  additions  $> 8 \mu\text{mol L}^{-1} \text{h}^{-1}$ ,  $^{13}\text{C}$  primary production ranged between 1.28 and 1.65  $\mu\text{mol L}^{-1} \text{h}^{-1}$ . The difference in  $^{13}\text{C}$ -primary production estimates between “GRC+0” effluent- $\text{NH}_4$  and “GRC+100” effluent- $\text{NH}_4$  addition represented a 22-27% decline in primary production.

The impact of  $\text{NH}_4$  additions on phytoplankton  $\text{NH}_4$  uptake also differed between  $\text{NH}_4\text{Cl}$  and effluent- $\text{NH}_4$  treatments. The relationship between phytoplankton  $\text{NH}_4$  uptake versus  $\text{NH}_4$  concentrations (as effluent  $\text{NH}_4$  or  $\text{NH}_4\text{Cl}$ ) was investigated using specific  $\text{NH}_4$  uptake,  $V$  ( $\text{NH}_4$  uptake normalized to particulate organic nitrogen in the sample, analogous to a specific growth rate, at “balanced” growth) in order to evaluate nutrient kinetic relationships (i.e. Michaelis-Menten formulation). The data fit the Michaelis-Menten equation reasonably well at low concentrations but data at higher  $\text{NH}_4$  concentrations deviated from the model expectation. A theoretical maximum  $\text{NH}_4$  uptake rate was calculated (conservatively, dotted line, Fig 9) but confidence in this value is low and the experiment should be repeated. Phytoplankton  $\text{NH}_4$  uptake responded positively to  $\text{NH}_4\text{Cl}$  additions (Table 28, Fig. 8) and could be modeled as a classical Michaelis-Menten response (Fig. 9). In contrast, phytoplankton  $\text{NH}_4$  uptake initially showed a positive response to additions of effluent- $\text{NH}_4$  to an effluent- $\text{NH}_4$  addition of 8  $\mu\text{mol L}^{-1}$  but then declined by 29% at 100  $\mu\text{mol L}^{-1}$  compared to maximum phytoplankton N uptake. This decline in phytoplankton  $\text{NH}_4$  uptake as well as the minimum effluent- $\text{NH}_4$  addition at which the decline begins to occur is consistent with the decline in primary production described above (Table 26 and 27, Fig. 8).

Increasing concentrations of either effluent or  $\text{NH}_4\text{Cl}$  caused a decrease in  $\text{NO}_3$  uptake by GRC phytoplankton (Table 27). With no  $\text{NH}_4$  additions,  $\text{NO}_3$  uptake was 0.036 to 0.038  $\mu\text{mol N L}^{-1} \text{h}^{-1}$ . Phytoplankton  $\text{NO}_3$  uptake was reduced to 0.006 – 0.007 with 100  $\mu\text{mol N L}^{-1} \text{h}^{-1}$  (Table 27). The decrease in  $\text{NO}_3$  uptake was evident even at the some of the lowest additions (0.5  $\mu\text{mol L}^{-1} \text{NH}_4$ ); at the highest  $\text{NH}_4$  concentration addition (100  $\mu\text{mol NH}_4 \text{L}^{-1}$ ) phytoplankton  $\text{NO}_3$  was

reduced by 80% compared to control samples with no addition (Table 27). The total N uptake declined from a peak of  $0.165 \mu\text{mol L}^{-1} \text{h}^{-1}$  (at  $+0.25 \mu\text{mol NH}_4 \text{L}^{-1}$ ,  $\rho\text{NH}_4 = 0.132 \mu\text{mol L}^{-1} \text{h}^{-1}$ ,  $\rho\text{NO}_3 = 0.033 \mu\text{mol L}^{-1} \text{h}^{-1}$ ) to  $0.078 \mu\text{mol L}^{-1} \text{h}^{-1}$  (at  $100 \mu\text{mol L}^{-1}$  effluent- $\text{NH}_4$ ,  $\rho\text{NH}_4 = 0.071 \mu\text{mol L}^{-1} \text{h}^{-1}$ ,  $\rho\text{NO}_3 = 0.007 \mu\text{mol L}^{-1} \text{h}^{-1}$ ). A reduction of total N uptake at high  $\text{NH}_4$  concentrations is consistent with the April 2009  $\text{NH}_4\text{Cl}$  addition experiment results.

## 5.0 Discussion

Analysis of long-term trends in environmental parameters, including nutrients and nitrogen speciation provide insight into potential bottom-up controls on phytoplankton biomass in the San Francisco Estuary (SFE) Delta (e.g. Jassby, 2008; Glibert, 2010). These studies result in an integrated view of ecosystem-level changes and help to elucidate the primary drivers of the observed declines in phytoplankton that have been tied to collapse of the pelagic organism decline (POD) species (Sommer et al., 2007). One limitation of such integrative analysis of long term monitoring data is the potential that more subtle, but nonetheless important, changes in bottom-up drivers of phytoplankton growth will be masked by the complex interaction of several drivers operating together to impact the POD (Sommer et al., 2007). The goal of the present study was to investigate the potential for anthropogenic  $\text{NH}_4$  loading in the SFE to act as a bottom-up control on phytoplankton blooms (Wilkerson, et al 2006; Dugdale et al 2007; Glibert, 2010). The study was designed to look at three time and spatial scales (i.e. in situ measurements during river transects, 96-hr “grow-out” experiments, and 4-hr bottle incubations with manipulated  $\text{NH}_4$ ) and relies, in part, on phytoplankton physiology (i.e. primary production rates and phytoplankton N uptake) to provide a more sensitive indicator of environmental stress. The strength of using phytoplankton physiology as an indicator of environmental stress is that individual environmental stressor effects can potentially be detected on time scales of minutes to hours. The reliance on changes in phytoplankton biomass (or chlorophyll-a) or shifts in phytoplankton community composition as indicators of environmental stress require time scales of days to weeks – over these time scales interaction of multiple environmental stressors likely mask the contribution that an individual stressor makes to overall declines in phytoplankton. The results presented here are an attempt to constrain the role that anthropogenic  $\text{NH}_4$  loading and subsequent elevated  $\text{NH}_4$  concentrations play as a bottom-up control on phytoplankton in the Sacramento River.

*In situ* measurements made during the five Sacramento River transect surveys, and those completed by Foe et al. (2010) help to elucidate in a broad sense the environmental setting in the Sacramento River (i.e. nutrient concentrations, phytoplankton biomass and in situ primary production and phytoplankton N uptake). 96-hr “grow-out” experiments provide results on time scales of days whereas the 4-hr incubation experiments provide results on time scales of minutes to hours. Because of the differences in temporal and spatial scales of each of these approaches it is not surprising that interpretation of results from each approach leads to different and sometimes conflicting conclusions. Insight into the potential effect of  $\text{NH}_4$  on phytoplankton biomass, primary production and phytoplankton N uptake can be gained from considering each of the approaches used here.

## 5.1 SRWTP Effect on Inorganic Nutrient Distributions in the Sacramento River

River characterizations show that while nutrient concentrations varied substantially in the Sacramento River on a seasonal basis, discharge from the SRWTP has a large effect on river nutrient concentrations, particularly for  $\text{NH}_4$  and  $\text{PO}_4$ . Secondly,  $\text{NH}_4$  from the SRWTP outfall appears to influence the spatial distribution of elevated  $\text{NH}_4$ ,  $\text{NO}_2$ , and  $\text{NO}_3$  at locations downstream of the SRWTP, likely as the result of nitrification (Fig. 7). We cannot further assess nitrification rates with the current dataset available but additional studies will be initiated to better constrain this biogeochemical pathway for inorganic nitrogen in the Sacramento River.

Because of the limited number of data points for  $\text{NH}_4$  concentrations collected at each station during this study ( $n = 5$ ), and the large range in values encountered during transect surveys, mean  $\text{NH}_4$  concentrations were not calculated for the Sacramento River immediately downstream of the SRWTP outfall (i.e. at RM-44 and HOD). However, estimates of mean river  $\text{NH}_4$  concentrations are necessary to determine “environmental relevance” for results obtained during short duration bottle incubations (i.e. “clean”  $\text{NH}_4\text{Cl}$  and effluent- $\text{NH}_4$  addition experiments). Specifically, are the concentrations used in the short duration bottle incubations similar to  $\text{NH}_4$  concentration found in the Sacramento River downstream of the SRWTP outfall? The Central Valley Regional Water Quality Control Board (CVRWQCB) surveyed  $\text{NH}_4$  concentrations in the river downstream of SRWTP over 16 months from March 2009 to February 2010 (Foe, 2010). The CVRWQCB found  $\text{NH}_4$  concentrations at HOD averaged  $32.99 \pm 7.40 \mu\text{mol L}^{-1}$  (95% CI,  $n = 16$ ) (Foe 2010, Table 1A). Similar to the results presented here, variability in  $\text{NH}_4$  concentrations collected by CVRWQCB at HOD was large; ranging between 2.86 to  $50.71 \mu\text{mol L}^{-1}$  (more than a factor of 17-fold) with no pronounced seasonal pattern. The SRWTP also collected samples weekly between July 2008 and June 2009 at HOD for  $\text{NH}_4$  analysis (Fig 10). The SRTWP dataset also shows large annual variation in  $\text{NH}_4$  ( $20.71$  to  $92.86 \mu\text{mol L}^{-1}$ ) with a mean  $\text{NH}_4$  of  $47.86 \pm 5.70 \mu\text{mol L}^{-1}$  (95% CI,  $n = 49$ ). In most months  $\text{NH}_4$  exceeded  $50 \mu\text{mol L}^{-1}$  at HOD (the exceptions were August 2008 (maximum  $\text{NH}_4 = 41.43 \mu\text{mol L}^{-1}$ ) and May 2009 (maximum  $\text{NH}_4 = 29.29 \mu\text{mol L}^{-1}$ )). Finally, Larry Walker and Associates calculated  $\text{NH}_4$  concentrations downstream of the SRWTP discharge from records of  $\text{NH}_4$  discharge and Sacramento River Flow and suggested mean  $\text{NH}_4$  of  $39.01 \pm 1.38$  (95%CI,  $n = 365$ ) and a range of 10.93 to  $77.36 \mu\text{mol L}^{-1}$  during the period between July 2008 and June 2009 (SRCSD, 2010). The same modeling study suggests increasing  $\text{NH}_4$  concentrations at HOD over the POD years (2002-2009) of approximately  $2 \mu\text{mol L}^{-1} \text{yr}^{-1}$  and a median value of  $25.7 \mu\text{mol L}^{-1}$  over the entire period. Each of these approaches clearly show that the  $\text{NH}_4$  concentration range used in the short duration  $\text{NH}_4$  incubation experiments ( $1$  to  $50 \mu\text{mol L}^{-1}$  and  $1$  to  $100 \mu\text{mol L}^{-1}$ ) are “environmentally relevant” representing  $\text{NH}_4$  concentrations regularly experienced by phytoplankton in the Sacramento river between the SRWTP outfall and HOD, approximately 10 km downstream of the discharge.

While samples for total dissolved nitrogen (TDN) and dissolved organic nitrogen (DON) were collected and analyzed during this study by the SRTWP, these results were not available at the time of the report. Foe et al. (2010) presented TND and DON from their 16 month long survey of river nutrient chemistry at HOD.  $\text{NH}_4$  represented  $60\% \pm 12$  ( $\pm 95\%$  CI,  $n = 16$ ) of the TDN (range 4 to 92%). In contrast DON contributed between 5 and 9% of the N to TDN (removing on sampling data, March 16) (Foe et al., 2010, Table 1A). In  $>2/3$  of the sampling events, DON increased between GRC and HOD presumably as a result of SRWTP discharge. In 10 of 16 sampling events, DON decreased between HOD and Walnut Creek. The DON decrease

averaged  $4.85 \mu\text{mol L}^{-1}$  or roughly 35% of the DON concentration at HOD. The decrease in DON may have been through ammonification (DON conversion to  $\text{NH}_4$ ), contributing a relatively small amount of  $\text{NH}_4$  (ca.  $5 \mu\text{mol l}^{-1}$ ) to the  $\text{NH}_4$  pool.

## ***5.2 SRWTP Effect on Phytoplankton N Uptake Rates***

Compared to the three stations (I80, OAK, GRC) upstream of the SRWTP, phytoplankton  $\text{NH}_4$  uptake increased immediately downstream of the wastewater discharge (at RM-44), presumably in response to higher  $\text{NH}_4$  concentration supplied via SRWTP. Upstream of SRWTP  $\text{NH}_4$  concentrations were typically low ( $<1 \mu\text{mol L}^{-1}$ ) and so phytoplankton  $\text{NH}_4$  uptake may have been  $\text{NH}_4$ -limited. Experimental additions of  $\text{NH}_4\text{Cl}$  up to  $+50 \mu\text{mol L}^{-1}$  resulted in a decrease in phytoplankton  $\text{NH}_4$  uptake during April 2009 whereas experimental additions of  $\text{NH}_4\text{Cl}$  made in May 2009 enhanced phytoplankton  $\text{NH}_4$  uptake up to ca.  $4 \mu\text{mol NH}_4 \text{ L}^{-1}$  (i.e. apparent saturation for  $\text{NH}_4$  in the May 2009 Sacramento River N uptake kinetics experiment). This would imply that  $\text{NH}_4$  concentrations greater than  $4 \mu\text{mol N L}^{-1}$  should not lead to further enhancement of phytoplankton  $\text{NH}_4$  uptake. SRWTP effluent (tracked as “effluent- $\text{NH}_4$ ”) led to a decrease in phytoplankton  $\text{NH}_4$  uptake at concentrations greater than  $4 \mu\text{mol N L}^{-1}$ ; in the one experiment conducted using effluent- $\text{NH}_4$  additions, phytoplankton  $\text{NH}_4$  uptake decreased by 29% at  $100 \mu\text{mol “effluent NH}_4\text{“ L}^{-1}$  when compared to the maximum value observed. The concentration threshold of  $8 \mu\text{mol N L}^{-1}$  represents a wastewater effluent dilution of greater than 200:1 (based on an undiluted effluent  $\text{NH}_4$  concentration of  $1933 \mu\text{mol N L}^{-1}$ ), significantly higher dilution than required under the current SRWTP permitting ([http://www.waterboards.ca.gov/centralvalley/board\\_decisions/adopted\\_orders/sacramento/5-00-188\\_npdes.pdf](http://www.waterboards.ca.gov/centralvalley/board_decisions/adopted_orders/sacramento/5-00-188_npdes.pdf)).  $\text{NH}_4$  concentrations supplied to the Sacramento River by SRWTP as wastewater effluent resulted in  $\text{NH}_4$  consistently  $>4 \mu\text{mol L}^{-1}$  observed at stations downstream of the SRWTP during river characterizations.

Phytoplankton  $\text{NO}_3$  uptake was high at stations upstream of the SRWTP but decreased abruptly to near detection limits ( $0.02 \mu\text{mol L}^{-1} \text{ d}^{-1}$ ) at stations downstream of the SRWTP. The shut down of phytoplankton  $\text{NO}_3$  uptake appears to be the result of the well described phenomenon of  $\text{NH}_4$  inhibition of phytoplankton  $\text{NO}_3$  uptake. During all manipulation experiments where  $\text{NH}_4$  was added to river water (either as  $\text{NH}_4\text{Cl}$  or SRWTP effluent- $\text{NH}_4$ ; i.e. manipulated grow-outs, clean  $\text{NH}_4\text{Cl}$  addition and SRWTP effluent addition experiments) phytoplankton  $\text{NO}_3$  uptake was always reduced to near detection limits with  $\text{NH}_4$  additions as low as  $<1 \mu\text{mol NH}_4 \text{ L}^{-1}$  indicating that the phytoplankton community was sensitive to  $\text{NH}_4$  concentrations, consistent with previous findings for the northern SFE (Wilkerson et al., 2006; Dugdale et al., 2007); this condition was observed during all sampling dates.

Clearly SRTWP discharge reduces phytoplankton access to  $\text{NO}_3$ . There remains some uncertainty as to the impact of the reduction of phytoplankton  $\text{NO}_3$  uptake on primary production and nitrogen processing in the Sacramento River. Dugdale et al (2007) hypothesized that fast growing coastal diatoms were more sensitive to  $\text{NH}_4$  inhibition of  $\text{NO}_3$  uptake in the northern SFE and suggested that anthropogenic  $\text{NH}_4$  loading to the estuary likely reduces the relative importance of diatoms during spring bloom events. We cannot fully evaluate potential shifts in the phytoplankton community with the present dataset (see below) but phytoplankton samples were collected and preserved for later analysis.

Table 28 summarizes the observed impacts of effluent and  $\text{NH}_4\text{Cl}$  additions on phytoplankton nitrogen uptake during experiments conducted using  $\text{NH}_4\text{Cl}$  and a composite sample of effluent from SRWTP. Primary production and phytoplankton  $\text{NH}_4$  uptake appeared to be negatively impacted by SRWTP effluent at additions  $>8 \mu\text{mol NH}_4$ . In the one experiment with SRWTP conducted primary production was by up to ca. 30% with additions of  $100 \mu\text{mol L}^{-1}$  effluent- $\text{NH}_4$  and phytoplankton  $\text{NH}_4$  uptake was reduced by nearly 1/3. The impact of additions of  $\text{NH}_4$  (either as  $\text{NH}_4\text{Cl}$  or effluent  $\text{NH}_4$ ) on phytoplankton  $\text{NO}_3$  uptake was consistent with a reduction of 80% of phytoplankton  $\text{NO}_3$  uptake compared to the controls (with no  $\text{NH}_4\text{Cl}$  added). Additions of  $\text{NH}_4$  as effluent or  $\text{NH}_4\text{Cl}$  result in reduced uptake of DIN at concentrations  $>4$  to  $8 \mu\text{mol L}^{-1}$ . The reductions in phytoplankton N uptake shown during the one experiment with SRWTP effluent provide evidence for a potential effect of SRWTP additions. However, this experiment should be repeated with the impacts established here validated.

### ***5.3 SRWTP Effect on Primary Production and Phytoplankton Blooms***

Primary production estimates obtained during the river transects show a decline in productivity from the City of Sacramento south to Rio Vista. The decline in primary production was consistent with the decrease in chlorophyll-a, which raises the question of whether the change in primary production is a function of a change in biomass or of photosynthetic activity. Chlorophyll-a normalized primary production (P/B, Tables 9, 12, 15, 18) was calculated for stations during each of the transects where primary production estimates were made. Patterns in P/B were not consistent spatially across cruises. During March and April 2009 P/B values were depressed slightly compared to upstream stations. During November and May the opposite trend or no trend was apparent. The patterns observed in March and April are consistent with the experimental results obtained with effluent addition experiments (May 2009, Section 4.5) where primary production rates decreased at elevated SRWTP effluent  $\text{NH}_4$  additions. However, the validity of this type of analysis is very sensitive to low chlorophyll-a concentrations; at these lower chlorophyll-a concentrations sampling artifacts and associated error may undermine interpretation of *in situ* phytoplankton physiology.

Results from experimental grow-outs suggest that after removing light limitation phytoplankton bloom magnitude in the Sacramento River at RM-44 and GRC is likely determined by dissolved inorganic nitrogen (DIN) availability. Grow-out experiments conducted downstream of the SRWTP (RM-44) produced more chlorophyll-a than experimental grow-outs conducted upstream of the SRWTP (GRC). Phytoplankton used additional DIN, either as  $\text{NO}_3$  or  $\text{NH}_4$  in experiments conducted with water from GRC, or in the form of  $\text{NH}_4$  supplied in the wastewater effluent (at RM-44) to produce greater biomass. Water collected at RM-44 and used in “grow-out” experiments may not be completely representative of the Sacramento River after SRWTP discharge has been introduced. Routinely, the highest  $\text{NH}_4$  concentrations were not found at RM-44 but further downstream at HOD suggesting that wastewater effluent was not completely mixed at RM-44 (D. Engle, pers. comm.). During separate Sacramento River surveys conducted in spring 2009, Parker, et al (in review) found a depression in primary production and phytoplankton  $\text{NH}_4$  uptake with increasing  $\text{NH}_4$  concentrations at 6 stations between RM-44 and Isleton also suggesting that using water collected at RM-44 for “grow-out” enclosures may not have fully captured the influence of SRWTP in the Sacramento River.

Additions of  $\text{NH}_4\text{Cl}$  to water collected at GRC, at additions of  $0.25 \mu\text{mol L}^{-1}$  to  $100 \mu\text{mol L}^{-1}$  during May 2009 showed no effect on primary production during 4-hr experiments suggesting that phytoplankton uptake potential was not N-limited in the Sacramento River above the SRWTP discharge location. If phytoplankton were N-limited, primary production and phytoplankton N uptake would have increased in response to additions of  $\text{NH}_4$ . The apparent N-limitation noted in July 2008 grow-out experiments conducted using water from GRC, occurred around 48-hr and under saturating irradiance (50% of surface PAR). The irradiance values and biomass accumulation in grow-out experiments are not encountered *in situ* in the Sacramento River. *In situ* conditions, including low irradiance conditions and phytoplankton biomass losses (e.g. zooplankton grazing or sinking phytoplankton cells (Foe et al., 2010) are eliminated during grow-out experiments. In contrast to the results from May 2009, during April 2009 additions of  $\text{NH}_4\text{Cl}$  (up to  $+50 \mu\text{mol L}^{-1}$ ) did result in decreased primary production. During May 2009, experimental additions of SRWTP effluent- $\text{NH}_4$  resulted in decreased primary production rates (in the one experiment the decrease was up to ca. 36% compared to the control) (Table 28); Similar to the results for phytoplankton  $\text{NH}_4$  uptake, the decline in primary production became evident at effluent- $\text{NH}_4$  concentrations greater than  $8 \mu\text{mol N L}^{-1}$ . The  $\text{NH}_4$  concentrations that were measured during the five transect surveys made during this study appear to be low compared to the more comprehensive sampling programs for  $\text{NH}_4$  by Foe et al (2010) and the SRWTP. Based on the more comprehensive measurements of  $\text{NH}_4$ , the  $\text{NH}_4$  concentrations that were tested during the effluent  $\text{NH}_4$  addition experiments and  $\text{NH}_4\text{Cl}$  appear to reflect  $\text{NH}_4$  concentrations *in situ* in the Sacramento River. Because of the April 2009 results, we cannot rule out an effect of  $\text{NH}_4\text{Cl}$  on primary production but the decrease in primary production that was observed with additions of effluent- $\text{NH}_4$  may be the result of  $\text{NH}_4$  or some unidentified component of the SRWTP discharge; if that was the case,  $\text{NH}_4$  in this experiment was a tracer of increasing concentrations of this toxicant.

It is unlikely that the decline in chlorophyll-a and fluoroprobe pigments that were observed along transects from the upper river to RM44 is the result of phytoplankton light adaption (i.e. changes in chlorophyll-a cell quota due to changes in the light field experienced by phytoplankton *in situ*) as flow cytometer particle counts declined along with chlorophyll-a. In addition, photic zone depths did not show a consistent trend of either increase or decrease moving downstream from I80 to RM-44 providing evidence of changes in light availability.

The degradation product of chlorophyll-a, phaeophytin, was measured during transects and provides insight into the declining patterns observed for chlorophyll-a in the Sacramento River (Fig. 11). Phaeophytin concentrations were relatively low upstream of the wastewater treatment plant (1 to  $\sim 3 \mu\text{g L}^{-1}$ ), equivalent to 30-40% of the chlorophyll-a concentration. Phaeophytin concentrations generally increased towards RM44 or HOD (while chlorophyll-a concentration consistently decreased) both in absolute and relative concentrations, representing 90-100% of the chlorophyll-a concentrations at RM-44 during July 2008 and April 2009. Downstream of RM44, phaeophytin and chlorophyll-a decreased at roughly the same rate and maintaining similar proportions. The patterns in chlorophyll-a and phaeophytin are less clear during March and May 2009 when river flows were high and the phaeophytin signal may have been diluted.

Phaeophytin is produced through the degradation of active chlorophyll-a; elevated phaeophytin is typically ascribed to zooplankton grazing on phytoplankton but phaeophytin can also be produced through the senescence of phytoplankton cells. Zooplankton grazing was not

assessed during the study and we are not aware of zooplankton studies for the Sacramento River so there is no means to test this potential mechanism to explain the phaeophytin pattern but increased zooplankton activity downstream of Sacramento could explain the patterns observed. The grazing hypothesis is puzzling as there is no clear reason to expect zooplankton grazing to be low at upstream stations with increased grazing toward the SRWTP, and relatively constant grazing pressure maintained at downstream stations. An alternative hypothesis is that chlorophyll-a was produced mainly at upstream locations with little additional *in situ* production of chlorophyll-a moving south of GRC. The increase in absolute phaeophytin and the relative increase in phaeophytin compared to chlorophyll-a may reflect the ongoing senescence of active chlorophyll-a with little new production of chlorophyll-a.

Foe et al. (2010) examined the relationship between the decline in chlorophyll-a and Sacramento River mean daily flow and 15-minute river velocity. The authors found a relationship between 15-minute instantaneous flow and the loss of chlorophyll-a, suggesting that the loss in chlorophyll-a may be the result of settling of phytoplankton cells and inability for phytoplankton cells to be resuspended. This plausible hypothesis still supports the contention that chlorophyll-a production occurs primarily upstream of the SRWTP with little *in situ* chlorophyll-a production at locations downstream of the SRWTP. Had there been sufficient chlorophyll-a production at downstream locations there would be a resupply of surface chlorophyll-a.

#### ***5.4 Phytoplankton Species Composition Changes as a Result of SRWTP Effluent (Including NH<sub>4</sub>) Discharge***

Flow cytometer data and size-fractionated chlorophyll-a concentrations provide a proxy for assessing changes in the phytoplankton community along the longitudinal extent of the Sacramento River covered during these transects. Based solely on size fractionated chlorophyll-a there does not appear to be consistent spatial patterns in the partitioning of chlorophyll-a into two size classes (>5- $\mu\text{m}$  and <5- $\mu\text{m}$  diameter cells). In general, the highest proportion of chlorophyll-a in >5- $\mu\text{m}$  cells appears to be in stations upstream of SRWTP (i.e. November 2008, March, April and May 2009) but this is not always the case (i.e. July 2008) and in general the percent differences are not large between stations. If these general trends were validated with additional sampling events it would be consistent with the hypothesis put forth by Dugdale et al (2007) in which larger cells (assumed to be diatoms) would be favored in the NO<sub>3</sub>-driven upper Sacramento River and smaller cells (i.e. flagellates, cyanobacteria) would be favored in the NH<sub>4</sub>-driven SRWTP influenced region of the River. Analysis of the archived phytoplankton samples would more fully elucidate any changes in phytoplankton community composition.

## **6.0 Recommendations for Future Studies**

### ***6.1 Determination of the Underlying Causes for Declining Chlorophyll-a Concentrations From the City of Sacramento to Rio Vista, CA.***

A critical feature, previously undescribed until this study, was the apparent decline in chlorophyll-a along the full extent of the north-south transect to Rio Vista. Based on the present results it is not clear whether the decline in chlorophyll-a is due in part to SRWTP and there may

be additional factors also responsible. More detailed characterization of this phenomenon, including full spatial extent (i.e. chlorophyll-a and phytoplankton uptake rate measurements beginning north of I80 in the Sacramento River to RIO) and phytoplankton counts (see below) are needed.

Hypotheses:

- 1) Phytoplankton are starved for nitrogen due to the shut-down of phytoplankton  $\text{NO}_3$  uptake and the impairment of phytoplankton  $\text{NH}_4$  uptake (suggested by the effluent addition experiment).
- 2) There is only localized production of chlorophyll-a at upstream stations (I80 to GRC). Downstream in proximity to the SRWTP phytoplankton are unable to maintain cell numbers.
- 3) Increased grazing rates of chlorophyll-a from upstream to downstream results in a loss of chlorophyll-a.
- 4) Changes in phytoplankton species composition brought about by the change from  $\text{NO}_3$  to  $\text{NH}_4$  supported production results in inherent growth rates that are too low to offset grazing and other loss rates.
- 5) Some unknown toxin is synthesized *in situ* or supplied to the Sacramento River, and gains potency downstream reaching a maximum near Rio Vista.

Detailed analysis of phytoplankton community composition and phytoplankton C and N uptake rates along the north to south transect would help to more fully characterize the potential effect of SRWTP effluent on phytoplankton responses in the Sacramento River. It must be noted that chlorophyll-a is not strictly biomass (mass in carbon) and variation in C : chlorophyll-a ratio can “mask” more subtle patterns in phytoplankton biomass and production within the Sacramento River. Using a Fast- Repetition Rate Fluorometer (FRRF) would reveal impairment to the photosystems as a result of changing nutrient or the presence of toxicants.

Further, results from the present study cannot address the potential for SRWTP effluent to act to negatively shape the phytoplankton community in the Sacramento River (i.e. reduce the abundance of nutritious taxa and increase the abundance of less desirable species). Again, samples for phytoplankton identification were collected and preserved from each of the river characterization stations and should be analyzed.

## ***6.2 Determination of the Underlying Causes for Variability in $\text{NH}_4$ Concentrations Downstream of the SRWTP Discharge at RM-44.***

The present results show that SRWTP discharge is a significant source of  $\text{NH}_4$  and  $\text{PO}_4$  to the Sacramento River. However, the highest concentrations of  $\text{NH}_4$  were not always observed immediately downstream of the effluent source (i.e. RM-44).

Hypotheses:

- 1) Inappropriate sampling of hydrographic features, i.e. a non-homogeneous field or incomplete mixing.
- 2) Ammonification of dissolved organic nitrogen in the effluent, i.e. incomplete secondary treatment.
- 3) Unknown source (e.g. sediment flux).

Future studies are needed to close the nutrient budget for downstream flow of  $\text{NH}_4$ ,  $\text{NO}_2$ ,  $\text{NO}_3$ , and DON. Measurements of these variables at cross sections (e.g. at RM-44 and HOD) along with bottom tracking ADCP (Acoustic Doppler Current Profiler) measurements should reveal the possibility of unaccounted for sources of nitrogen in addition to SRWTP. It should then be possible to link river flow/modeling, discharge records and nutrient, phytoplankton and bacterial processes in an effort to determine the relative importance of SRWTP discharge versus other nutrient sources and microbial processes in determining the distribution and concentration of inorganic nutrients (particularly nitrogen) in the Sacramento River. This type of study will be crucial in developing a comprehensive model of the fate of inorganic nutrients supplied to the Delta from SRWTP.

### ***6.3 Characterization of Phytoplankton Community Composition in Experimental Grow-outs with Varying DIN (i.e. $\text{NO}_3$ and $\text{NH}_4$ ) Composition.***

The experimental grow-out results presented here for GRC and RM-44 are in contrast to those previously found for experiments conducted in Suisun Bay and Rio Vista (re: Wilkerson presentation at  $\text{NH}_4$  Summit). Specifically, results from RM-44 grow-outs showed substantial phytoplankton growth by phytoplankton supplied with  $\text{NH}_4$  as their primary N source whereas earlier results from these other locations show delayed or no phytoplankton growth when  $\text{NH}_4$  was their primary N source. Experimental phytoplankton blooms from water collected at GRC (where  $\text{NO}_3$  was the primary N source for phytoplankton) provides a contrast to results obtained at RM-44 and the potential for detailed examination of how phytoplankton community composition is shaped by the form of inorganic nitrogen available (i.e. either  $\text{NH}_4$  or  $\text{NO}_3$ ).

Hypothesis:

- 1) Experimental phytoplankton blooms driven by  $\text{NH}_4$  result in nutritionally inferior phytoplankton species. Experimental phytoplankton blooms driven by  $\text{NO}_3$  result in nutritionally superior phytoplankton species (e.g. diatoms).
- 2) Additional sources of water, carrying phytoplankton inhibitors enters the Sacramento River near Rio Vista.

Samples for phytoplankton identification were collected and preserved from each of experimental grow-outs and should be analyzed.

### ***6.4 Determination of Underlying Causes of SRTWP Effluent Toxicity on Primary Production and Phytoplankton Nitrogen Uptake.***

While it unclear at this time whether  $\text{NH}_4$  (as  $\text{NH}_4\text{Cl}$ ) has a direct negative effect on the phytoplankton parameters that were assessed here (but see above, Section 6.1) it does appear that some other constituent(s) may be present in the SRWTP effluent that do result in negative effects on the phytoplankton parameters. These negative effects were observed at concentrations of  $\text{NH}_4$  that are almost certainly maintained within the Sacramento River downstream of the SRWTP discharge.

Hypotheses:

- 1) Elevated  $\text{NH}_4$  concentrations acts to suppress primary production, phytoplankton  $\text{NH}_4$  and  $\text{NO}_3$  uptake, leading to reduced phytoplankton biomass in the Sacramento River.

- 2) Elevated SRWTP discharge (traced with elevated  $\text{NH}_4$ ) acts to suppress primary production, phytoplankton  $\text{NH}_4$  and  $\text{NO}_3$  uptake, leading to reduced phytoplankton biomass in the Sacramento River.

Experiments need to be made to sequentially address the questions 1) is  $\text{NH}_4$  the only factor suppressing primary production in the river downstream of SRWTP (RM-44)? This could be addressed by removing  $\text{NH}_4$  to low levels (using phytoplankton or bacterial growth) and inoculating phytoplankton into to this “cleaned” water. 2) Is there trace metal toxicity that increases downstream from RM-44? Amendments of chelators or other techniques to remove potential toxicants (e.g. pesticides) are available and would help answer this question. Additional experiments with additions of  $\text{NH}_4\text{Cl}$  are needed to resolve the inconclusive results of the direct effect of  $\text{NH}_4$  on primary production and phytoplankton  $\text{NH}_4$  uptake.

1	<b>River Transects</b> – Characterizing the Sacramento River above and below the SRWTP (I-80 Bridge in Sacramento to Rio Vista) in July and November 2008, with nutrient concentrations, phytoplankton biomass.	Section 3.1
2	<b>Aging</b> Sacramento River water in the dark to observe if ammonium oxidation (nitrification) might be possible.	Section 3.3
3	<b>Experimental Grow-outs</b> in 2008 (WB-08-1, WB-08-2) with enclosed ambient water from above and near SRWTP and Central SFB (control) to measure nitrate and ammonium draw down and phytoplankton response by monitoring over 10 days for nutrient and chlorophyll-a concentrations.	Section 3.2
4	<b>Effluent Addition Experiment</b> in 2009 (WB-09-3 Effluents) in which diluted effluent from SRWTP was added to water collected upstream from SRWTP (Garcia Bend) and the effect on nitrate and ammonium uptake and primary productivity was measured.	Sections 3.5
5	<b>River Transects</b> – Characterizing the Sacramento River above and below the SRWTP (I-80 Bridge in Sacramento to Rio Vista) in March, April and May 2009, with nutrient concentrations, phytoplankton biomass and uptake rates.	Section 3.1
6	<b>Experimental Grow-outs</b> in 2009 (WB-09-1, WB-09-3) with enclosed ambient water from above (from Garcia Bend) and near SRWTP (from River Mile 44) and Central SFB (control) to measure nitrate and ammonium draw down and nutrient uptake and productivity by monitoring over 10 days for nutrient and chlorophyll-a concentrations. In addition, ammonium was added to Garcia Bend water and nitrate to River Mile 44 water such that the total initial DIN was equal.	Section 3.2
7	<b>Clean Ammonium Addition Experiment</b> in 2009 (WB-09-2) in which increasing ammonium concentrations were added to water collected upstream from SRWTP (Garcia Bend) and the effect on nitrate and ammonium uptake and primary productivity was measured.	Section 3.4
8	<b>Management and Data Report</b>	

Table 2: Sampling dates and experiments conducted during “Waterboard” Sacramento River sampling program (WBD) All transects were carried out in a north to south progression beginning at I80. (\*)transect was initiated from RM-44. (\*\*) Time of high water reported for the Sacramento River at Tower Bridge Gateway

Event Name	Date	High Water at Sacramento** (hh:mm) local time	Transect Start Time (hh:mm) local time	River Flow @Freeport (FPT) (cfs)	Number of Stations sampled	Additional Experiments
WBD08-1	July 21, 2008	09:02	08:39	13,033	7	10-d ambient “grow-out”
WBD08-2	November 12, 2008	06:18	08:25*	10,530	7	10-d ambient “grow-out”
WBD09-1	March 9, 2009	07:02	08:55	30,337	8	10-d manipulated “grow-out”
WBD09-2	April 6, 2009	05:47	08:33	12,035	8	“clean” NH <sub>4</sub> addition experiment
WBD09-3	May 8, 2009	07:08	08:24	25,900	8	10-d manipulated “grow-out”

Table 28 : Summary of observed impacts from SRWTP effluent and NH<sub>4</sub>Cl additions on primary production and phytoplankton NH<sub>4</sub> and NO<sub>3</sub> uptake during addition experiments conducted in April<sup>(1)</sup> and May<sup>(2)</sup> 2009. Effective concentration was the concentration at which any impact was first noted. SRWTP dilution equivalent is based on 1933 μmol L<sup>-1</sup> effluent concentration, as measured on the effluent supplied for the addition experiments.

	<b>Process</b>	<b>Effective Concentration</b>	<b>Effect</b>	<b>SRWTP Dilution Equivalent</b>
<b>Effluent</b>	Primary Production	(>8 μmol L <sup>-1</sup> ) <sup>2</sup>	22-36% decrease <sup>2</sup>	333 : 1
	NH <sub>4</sub> Uptake	(>4 μmol L <sup>-1</sup> ) <sup>2</sup>	29% decrease <sup>2</sup>	333 : 1
	NO <sub>3</sub> Uptake	(≥ 1 μmol L <sup>-1</sup> ) <sup>2</sup>	>80% decrease <sup>2</sup>	2000: 1
<b>NH<sub>4</sub></b>	Primary Production	Unclear <sup>1</sup>	Unclear <sup>1</sup>	None
	NH <sub>4</sub> Uptake	(>1 μmol L <sup>-1</sup> ) <sup>1</sup> Unclear <sup>2</sup>	34% <sup>1</sup> Unclear <sup>2</sup>	None
	NO <sub>3</sub> Uptake	(≥ 1 μmol L <sup>-1</sup> ) <sup>1</sup> (≥ 1 μmol L <sup>-1</sup> ) <sup>2</sup>	>80% decrease <sup>1</sup> >80% decrease <sup>2</sup>	2000 : 1
<b>Current SRWTP Dilution</b>				14 : 1

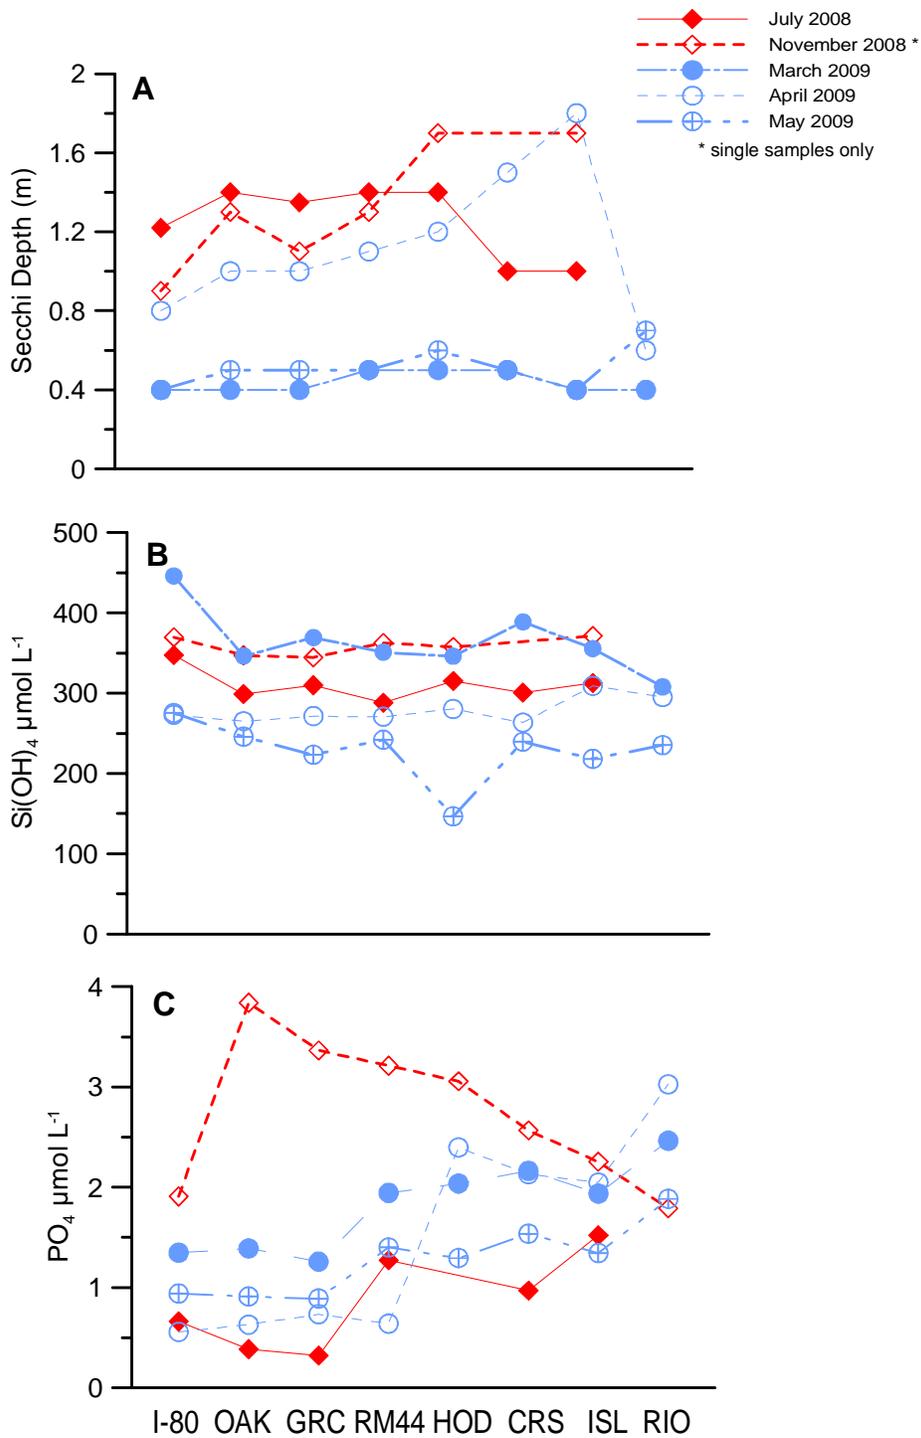

Figure 2: A) Secchi depth, B) silicate and C) phosphate concentrations along the Sacramento River during 5 transects completed between July 2008 and May 2009.

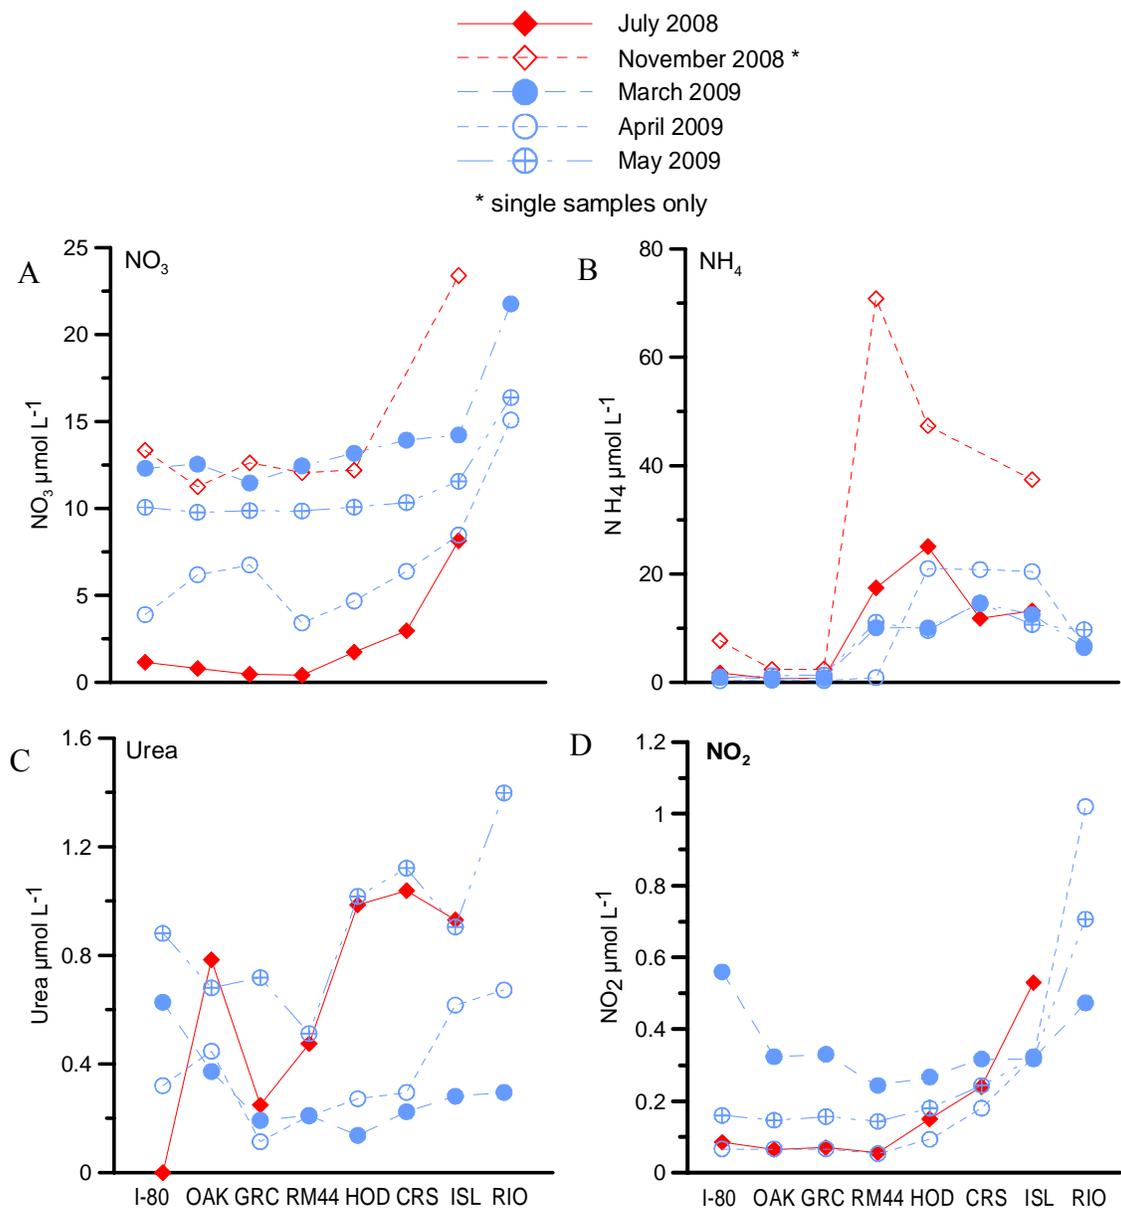

Figure 3: A)Nitrate, B)ammonium, C)urea and D)nitrite concentrations along the Sacramento River completed between July 2008 and May 2009.

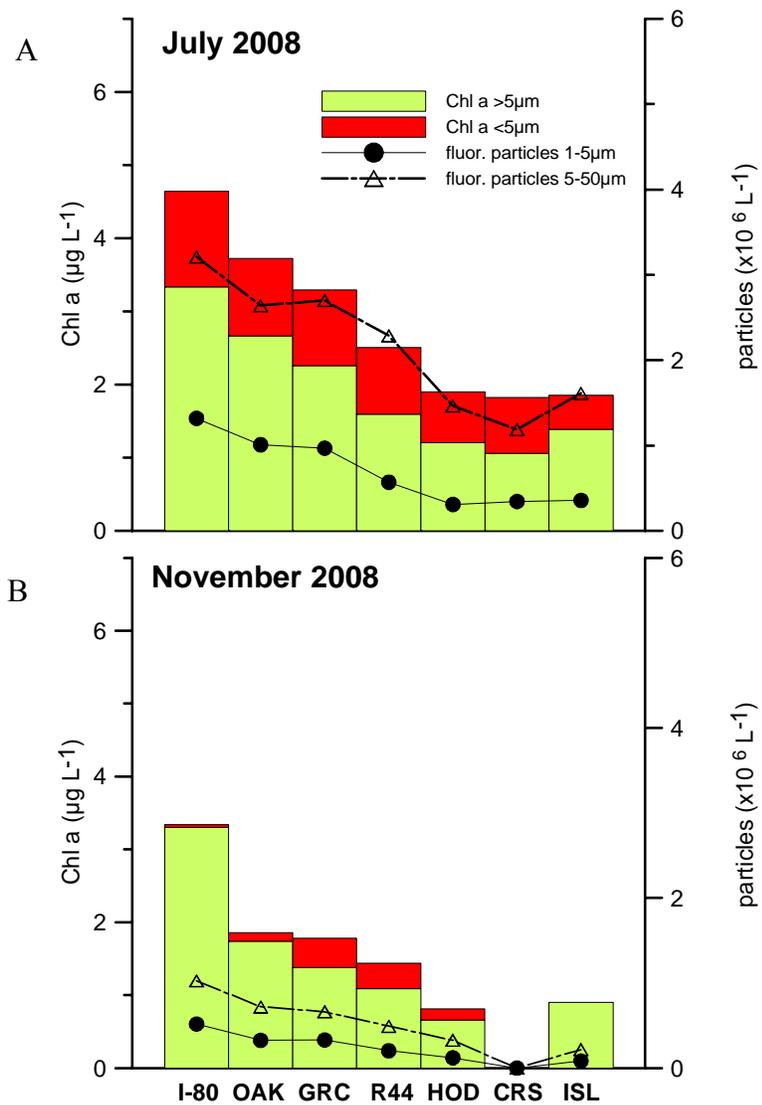

Figure 4: Chlorophyll concentrations for cells  $>5\mu\text{m}$  and  $<5\mu\text{m}$  in diameter and particle counts (1 to 5- $\mu\text{m}$  and 5 to 50- $\mu\text{m}$  in diameter) determined by flow cytometry. Samples were collected in the Sacramento River in A) July and B) November 2008.

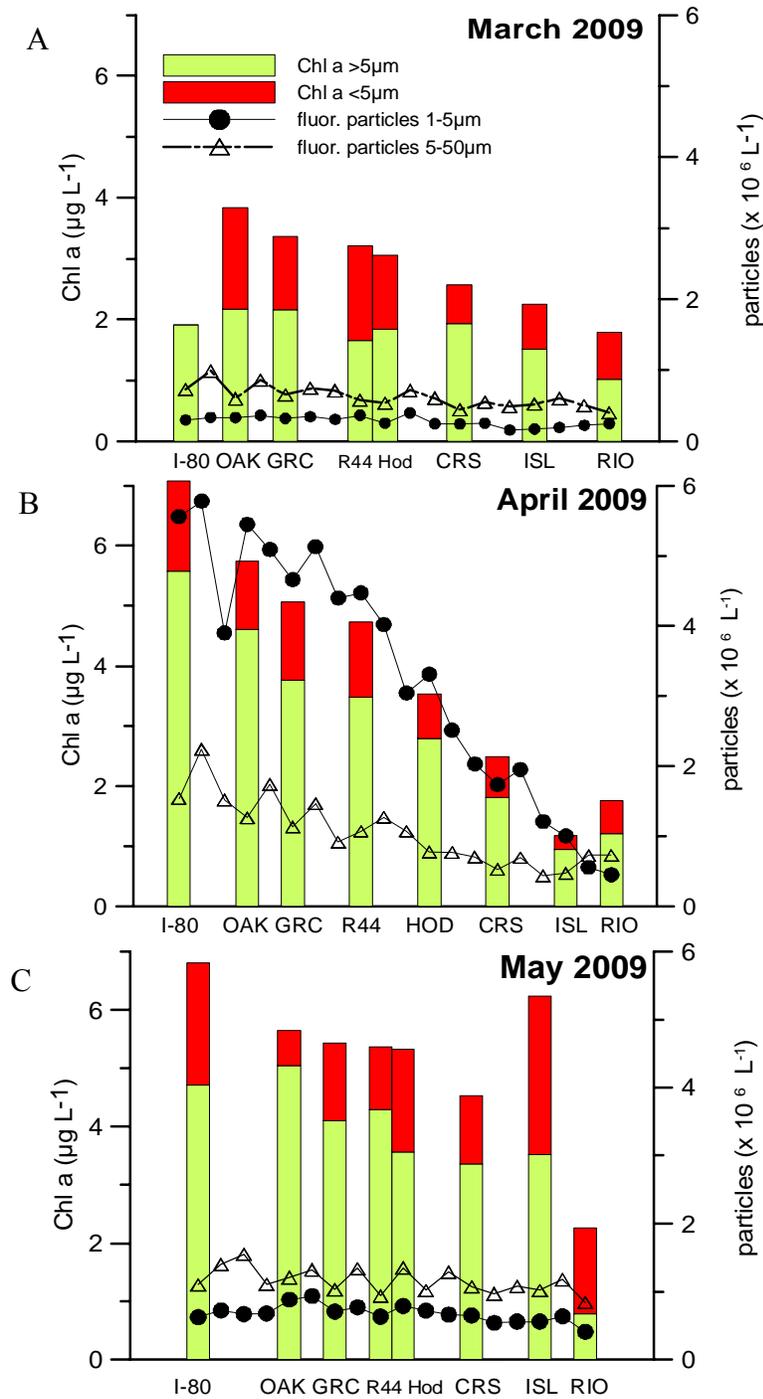

Figure 5: Chlorophyll concentrations for cells >5 $\mu\text{m}$  and <5 $\mu\text{m}$  in diameter and particle counts (1 to 5- $\mu\text{m}$  and 5 to 50- $\mu\text{m}$  in diameter) determined by flow cytometry. Samples collected during transect sampling in the Sacramento River during A) March, B) April, and C) May 2009.

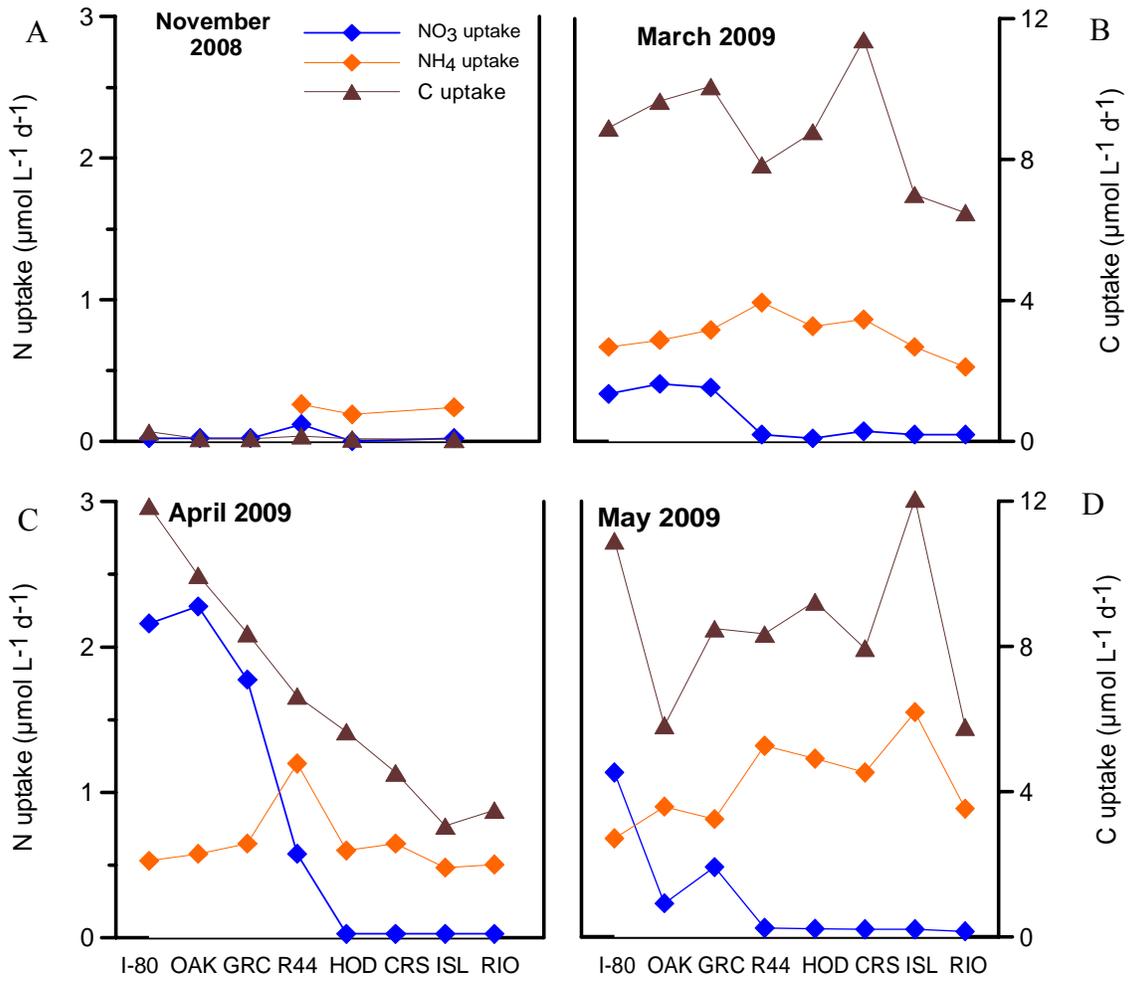

Figure 6: Primary production (C uptake) and phytoplankton nitrogen uptake rates (NH<sub>4</sub> and NO<sub>3</sub>) made during 24-hr incubations carried out during eight station transect surveys of the Sacramento River during A)November 2008, B)March 2009, C) April 2009, and D)May 2009.

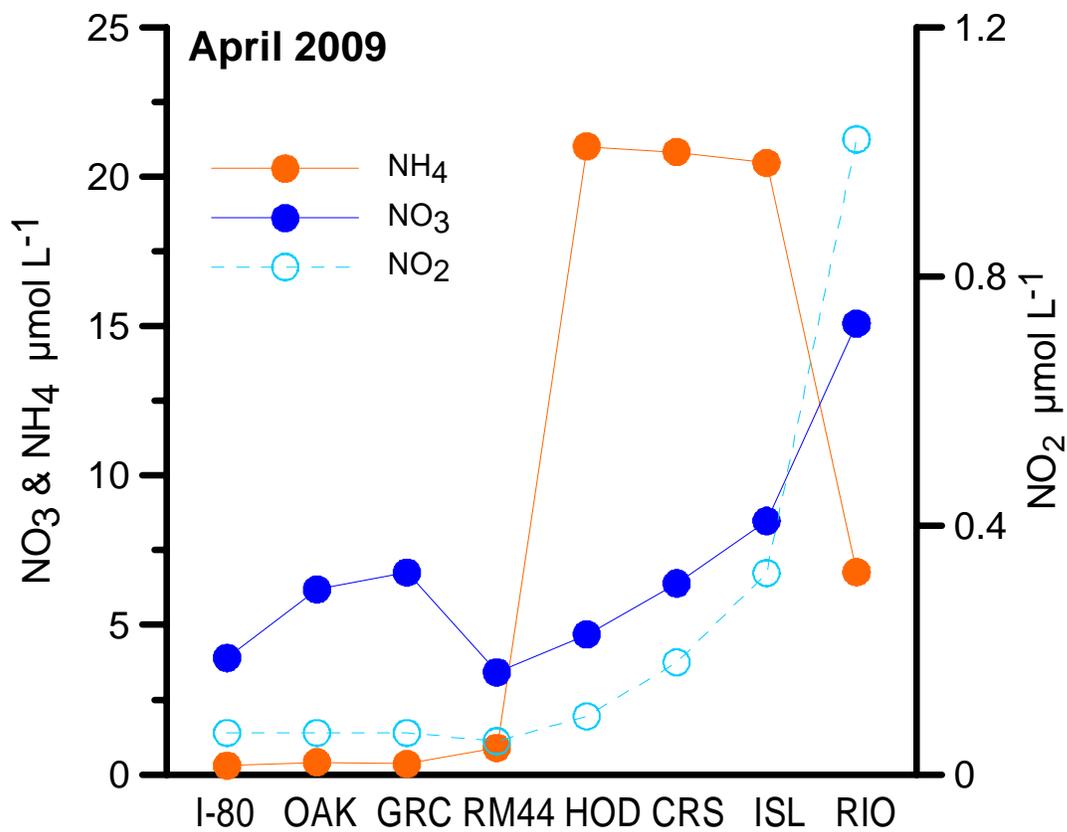

Figure 7: Ammonium (closed red), nitrate (closed blue), and nitrite (open blue) concentrations along the Sacramento River during April 2009.

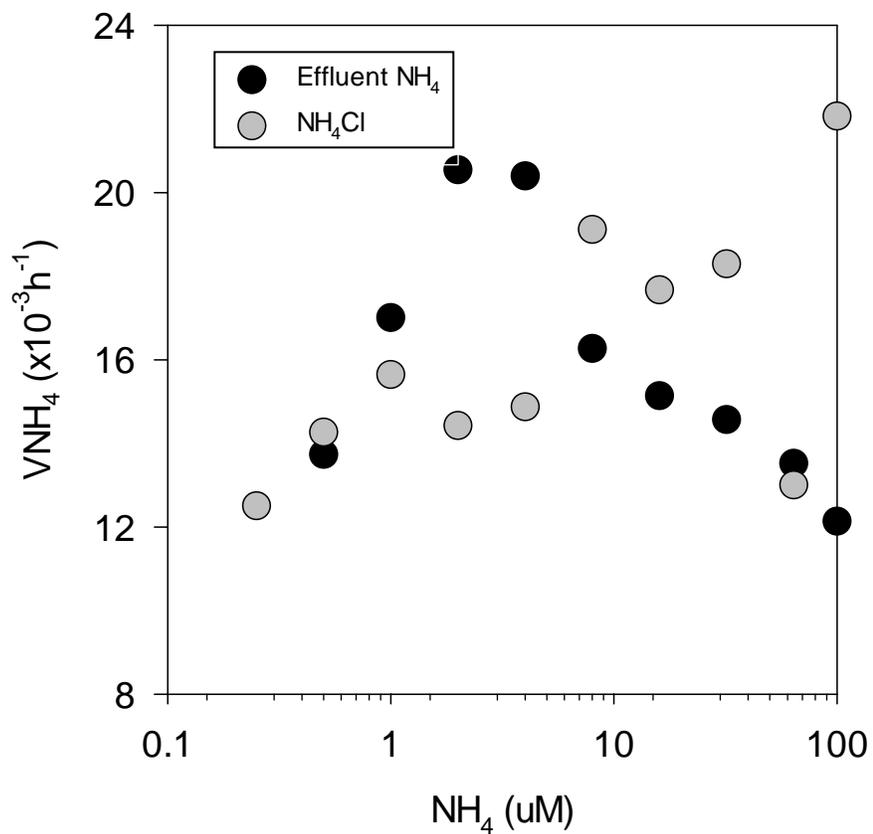

Figure 8: Specific  $\text{NH}_4$  ( $V_{\text{NH}_4}$ ,  $\times 10^{-3} \text{h}^{-1}$ ) uptake versus log  $\text{NH}_4$  concentration during the May 2009 effluent addition experiment. Closed circles are  $V_{\text{NH}_4}$  after exposure to experimental additions of effluent- $\text{NH}_4$ , gray circles are  $V_{\text{NH}_4}$  after exposure to experimental additions of  $\text{NH}_4\text{Cl}$ .

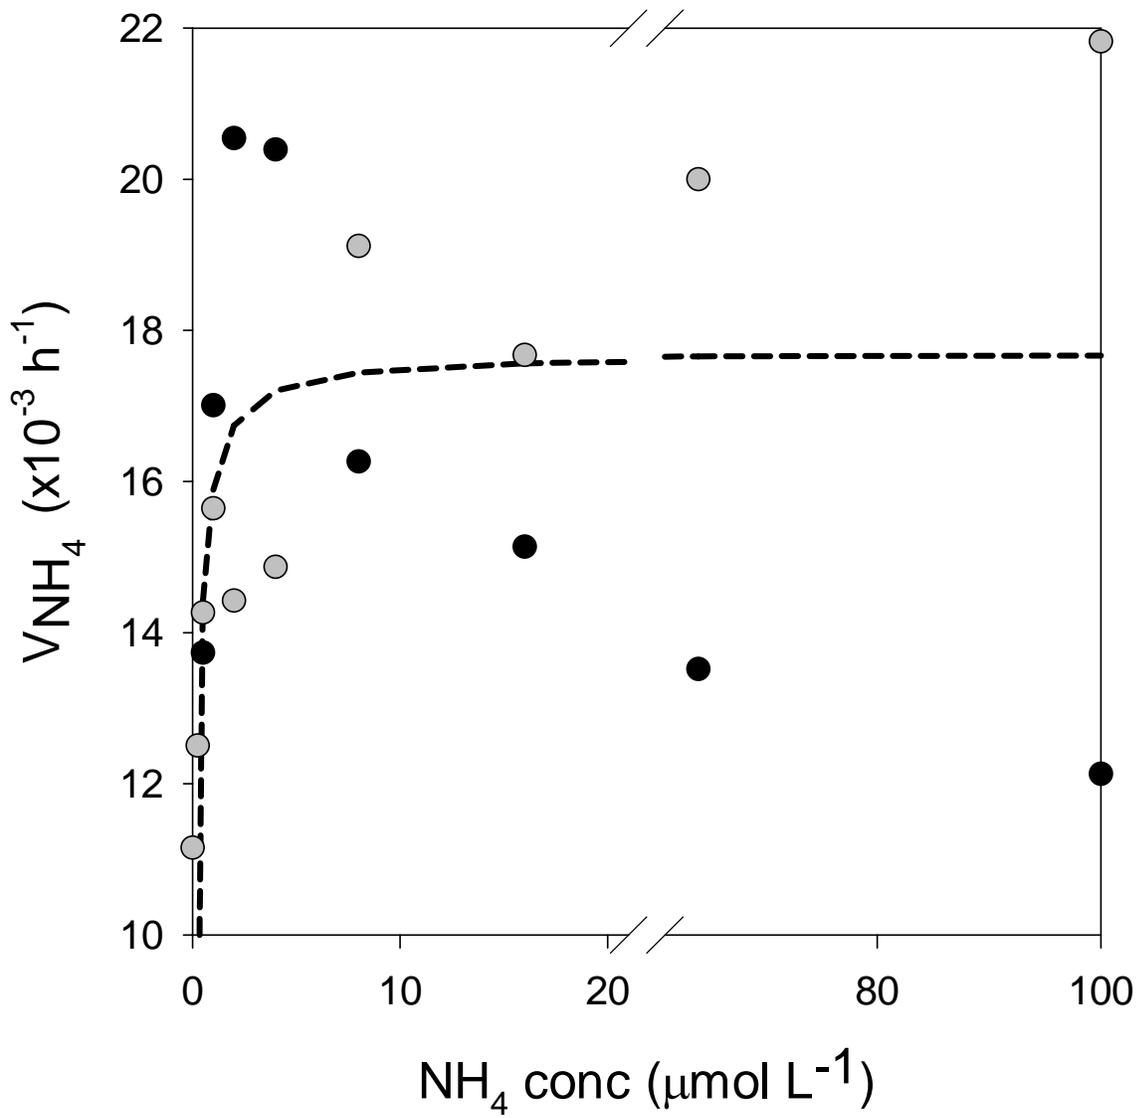

Figure 9: Ammonium uptake vs.  $\text{NH}_4$  showing Michaelis-Menten kinetics for the added  $\text{NH}_4$  incubations (grey circles).

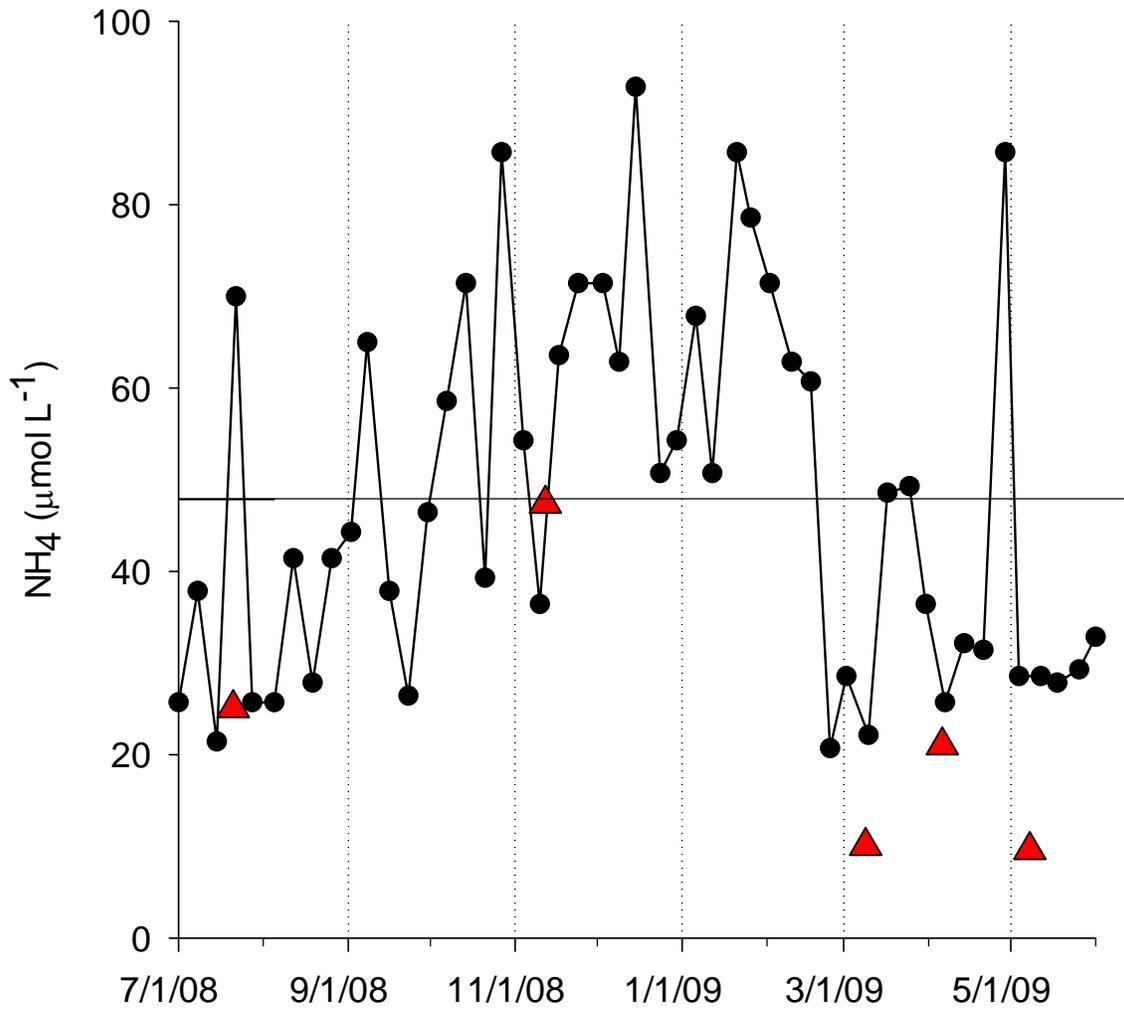

Figure 10: (Closed circles)  $\text{NH}_4$  concentration measured at HOD by SRWTP from July 2008 to June 2009. (Red triangles)  $\text{NH}_4$  concentrations measured by RTC during the five survey transects made of the Sacramento River in 2008 and 2009.

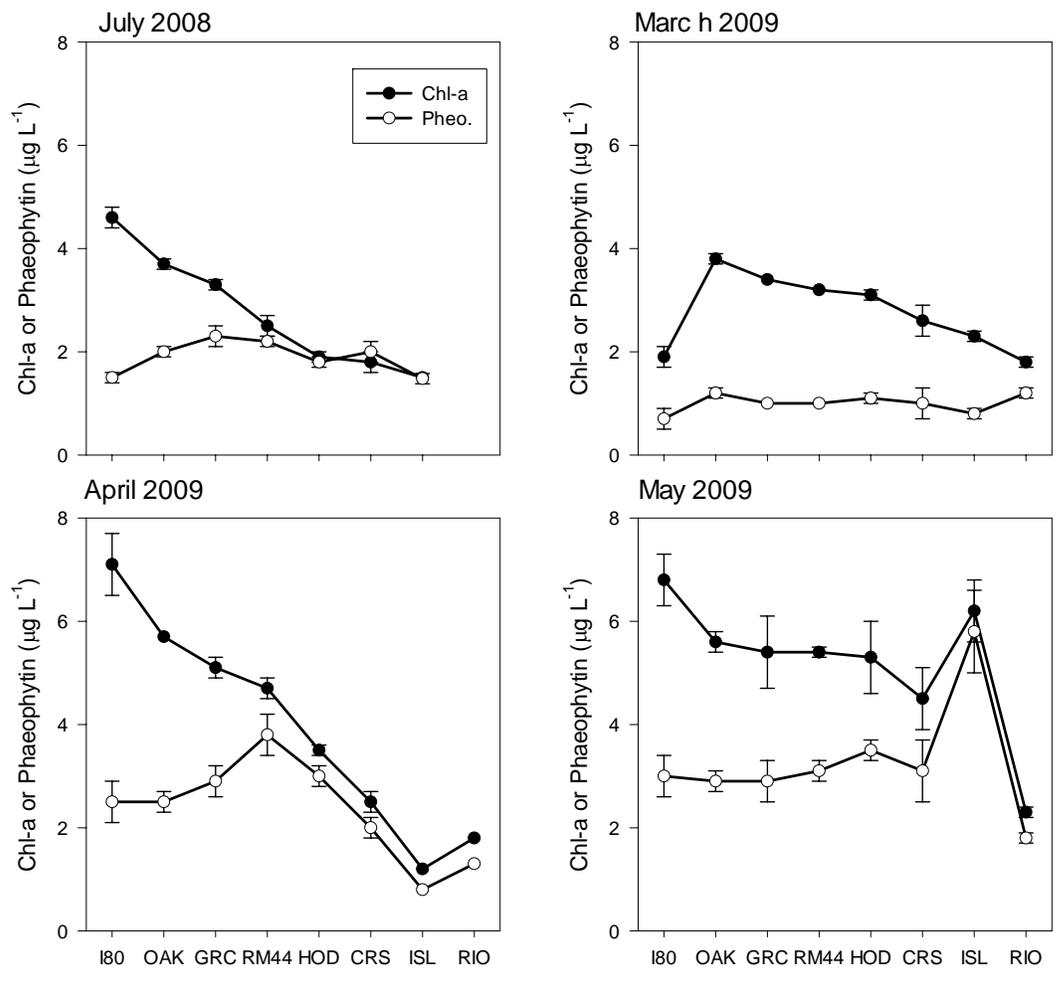

Figure 11: Chlorophyll-a and phaeophytin concentrations ( $\pm 95\%$  CL) from water samples collected along the Sacramento River on cruises between November 2008 and May 2009.
